AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

AAEA Annual Meeting
University of Illinois
Champaign-Urbana
27-30 July 1980

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

ISSN 0002-9092

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Economic Welfare and Food Safety Regulation: The Case of Mechanically Deboned Meat

Douglas W. McNiel

Mechanical deboning is a technology that allows red meat packers and processors to recover fragments of meat that are left on the bones of carcasses after hand trimming. The economic impact of alternative public policies, ranging from a ban on the use of mechanically deboned meat to a free market approach, is analyzed with a simultaneous equations supply-demand model of the markets for table and processed beef and pork. The results indicate that the loss in economic welfare to society, as well as the price and quantity effects associated with present restrictions, are not insignificant.

Key words: Economic welfare, food safety regulation, meat packing and processing, mechanically deboned meat, technological change.

Mechanical deboning is a technique for recovering the fragments of meat that remain on the bones of a carcass after hand trimming. In the mechanical deboning process, the bones and attached fragments of meat are ground up and fed into special deboning machines. The bone bits are screened out while the meat passes through. The result is a paste-like product called mechanically deboned meat (MDM) which, government regulations permitting, might be used as an ingredient in hot dogs, luncheon meats, and other processed meat products.

The mechanical deboning process is not new. It was developed for the Japanese seafood industry about twenty years ago and has been used in the U.S. poultry industry since 1965. More recent developments have established the technological feasibility of mechanically deboning red meats, primarily beef and pork. Red meats are being mechanically deboned now in at least twenty-nine foreign countries, including Australia, New Zealand, and Argentina. But mechanical deboning techniques have not been adopted widely by U.S. red meat processors because, until recently, U.S. Department of Agriculture (USDA) regulations never clearly defined the term "meat" to include or exclude MDM. Consequently, the associated edible red meat protein has been thrown away or sent along with the bones for inedible rendering, a low-valued use. This waste has been estimated by Field and others to amount to three to four pounds of meat per pork carcass and twelve to sixteen pounds per beef carcass.

Douglas W. McNiel is a former economist at the Economic Research Service, U.S. Department of Agriculture and is now an assistant professor in the Department of Economics at the University of Central Florida.

The author gratefully acknowledges the assistance of Joseph Jadlow, Ronald Moomaw, Kent Olson, Gerald Plato, Clifford Carman, and two anonymous referees for their constructive review comments.

Proposed Regulations

The USDA began formulating a policy on the use of MDM in November 1974, when it announced a pilot program for collecting technical data on mechanical deboning procedures (USDA 1974). Cooperating red meat processors who received USDA approval were allowed to produce MDM and use it in certain formulated meat food products. In April 1976, after evaluating data from the pilot program, the USDA formally proposed regulations to expand the definition of meat to include MDM and allow MDM to be used as an ingredient in processed meat products. At the same time, the USDA issued interim regulations providing for immediate production and distribution of MDM in processed meats for human consumption (USGSA 1976).

However, a public controversy developed

over the MDM regulations. After an unsuccessful appeal to the USDA for a ban on the production and use of MDM for human consumption, several consumer-oriented groups filed a suit in U.S. District Court contending that the USDA had failed to follow proper administrative procedure in issuing the temporary regulations. The court concurred and issued a temporary injunction against implementation of the interim rules (Community Nutrition Institute et al.). Subsequently, on 14 September 1976, the USDA ordered that the official mark of federal inspection could no longer be placed on MDM. This in effect stopped domestic manufacture and distribution of mechanically deboned red meat.

Health and Safety Issues

At the court's bidding, the USDA organized a select panel of government scientists to study the health and safety aspects of the use of MDM. The wholesomeness of MDM was questioned because it contains small amounts of pulverized bone powder and because of concerns that the heat generated in the process of producing MDM might create bacterial problems. Nutritional questions about MDM concerned its calcium content (indication of bone content), the amount of fat, the amount of protein, and the quality of protein. The labeling issue concerned specification of the ingredient statement, and whether the terms "beef" and "pork" (which are designations for hand-deboned meat) are appropriate for products containing MDM, or whether labeling terminology more descriptive of the processing technique was more appropriate.

After an intensive analytical program conducted in the laboratories of the USDA's Food Safety and Quality Service and other government agencies, the select panel concluded that (*a*) bone particle size obtained with mechanical deboners currently available presents no hazards to health; (*b*) no public health problem is posed by the presence or absence in the bone of trace elements, chemical, or pesticide residues; (*c*) a slight nutritional benefit is to be expected for most people from the calcium in MDM; (*d*) the lipid spectrum of MDM is comparable to the lipid pattern found in hand-deboned meats; (*e*) the microbiology of MDM presents no unique hazards and should not be a problem if good manufacturing practices and quality control programs are employed; and (*f*) the MDM content in food products should be labeled in the ingredients statement, so that persons who must stringently restrict calcium intake can avoid these products (USDA 1977).

Final Regulations

The select panel's findings and recommendations were incorporated into a new USDA proposal published in October 1977 (USGSA 1977). After another period of public comment and revision, final MDM regulations were published 20 June 1978, and became effective one month later (USGSA 1978). Under the final regulations, MDM is classified as a meat food product rather than as a class of meat. The MDM content is limited to 20% of all meat and meat by-products used in a processed meat food product. Parameters for minimum protein quantity and quality, maximum fat and calcium content, and standards for maximum particle size, quality control, and labeling are prescribed so that "there is no basis for expecting that the long-term use of (MDM) would pose health hazards or that the long-term effects would be any different from other processed meat food products . . ." (USGSA 1978, p. 26418). Despite this conclusion, the final regulations banned the use of MDM in fresh ground beef and pork, hamburger, fabricated steaks, and other products in which USDA concluded the consumer generally expects to find whole muscle meats (USGSA 1978).

Risks, Benefits, and Regulatory Bias

The decision to prohibit the use of MDM in a large segment of the processed meat market might reflect an alleged bias of food safety regulation (Campbell, Grabowski, Peltzman, Wardell). In this instance, the nutritional, health, and safety implications of MDM use were analyzed in great detail, but little or no attention was focused in the economic impact of the regulation. The amount of edible red meat protein recoverable via mechanical deboning was not analyzed carefully nor valued properly. In fact, the USDA's final statement of MDM rules strongly implied that economic considerations were irrelevant to the regulatory decision-making process (USGSA 1978).

What the USDA regulatory process failed to take into account is that with every food safety regulatory decision come certain benefits as

well as certain costs, including risks. The goal of public policy toward food safety and quality regulation should not be to minimize health risks, but rather to determine whether a particular policy measure would result in potential benefits to society which outweigh the potential costs including attendant health risks.

Food safety regulators may have difficulty recognizing the relevance of economic analysis for implementing this simply stated objective for several reasons. First and foremost is the problem that it is often very difficult to quantify the costs, benefits, and risks associated with a particular regulation. Second, the public and their representatives are only beginning to deal explicitly with the question of what additional health risk is acceptable to obtain additional net social benefits. A recent report by a National Academy of Sciences panel recommends that Congress set up a "multi-tiered" system of food safety standards in which risks would be weighed against benefits before any regulatory decision is made to ban or restrict a substance. Meanwhile, no additional risk has been a convenient, albeit economically costly, solution for legislators and regulators. Finally, Campbell and others have suggested that this bias occurs because those who make and administer the regulations are often confronted with the task of weighing possible large risks to a few persons against relatively small benefits to many people. The significance of a large risk and its possibly devastating impact on a few individuals may be more easily comprehended and publicized than the relatively small, dispersed benefits that may accrue to many individuals. To avoid blame or risk of losing public support, food safety regulators are likely to be overly cautious.

This regulatory bias may be justifiable up to a point, because large risks are difficult to assess. However, the loss of small benefits to individuals is also important, especially when the numbers affected are large. And, as Campbell notes, while the individual's risk or cost is a "private cost which can sometimes be insured against" or recovered monetarily through legal action, "the loss sustained by never receiving a benefit is a social, noninsurable cost against which there is no legal recovery" (Campbell, pp. 22–23).

If restrictions on the use of MDM are the result of regulatory bias, economic analysis could indicate at what cost to society is the goal of no additional risk being attained. Or, if MDM in fact presents no additional health risk, economic analysis could indicate at what cost to society is the "quality range" of meat food products being restricted.

Economic Analysis

The analysis that follows is confined to the markets for beef and pork, which together account for over 96% of per capita red meat consumption (USDA, *Livestock and Meat Situation*). Red meats reach consumers in two basic final forms, as table cuts and as processed meats. The potential effects of mechanical deboning are assessed at the retail level by assuming that the inclusion of MDM in processed meat products results in a pound-for-pound increase in the supply of processed meats. This is not an unrealistic assumption because (*a*) as a processed meat ingredient, MDM is subject to little or no shrinkage; and (*b*) the regulations for utilizing MDM stipulate that it not be detectable in the final product, so final product homogeneity is maintained.

Because MDM would enter the market as an ingredient in processed meat products, adoption of the technology will have differential impacts in the markets for table and processed meats. For this reason, the markets for beef and pork must be separated into submarkets for table and processed meats.[1] This division allows a direct examination of the economic effects of mechanical deboning, because the additional meat recovered by the technique will be used as an ingredient in processed meats and will affect table cuts only indirectly. To avoid repetition, the graphical analysis below is presented generally without regard to species of meat (beef or pork). Perfectly competitive markets are assumed throughout.

Primary Effects

When mechanical deboning techniques are adopted, each carcass mechanically deboned will yield, in addition to the previous amount of table cuts, more pounds of processed meats. Figure 1 shows the demand (dd') and supply (ss') of processed meats when the use of MDM in processed meats is restricted.[2] If

[1] The term table meats, as used in this study, refers to meats which are consumed in whole muscle form, except for cutting or slicing. The term processed meats refers to meats not consumed in whole muscle form. Included are processed products in which meat ingredients are ground, flaked, extruded, or mixed with other ingredients of animal and/or vegetable origin to form a new product.

[2] The supply curves in figure 1 are positioned to reflect the price inelasticity of the linear supply curves estimated below.

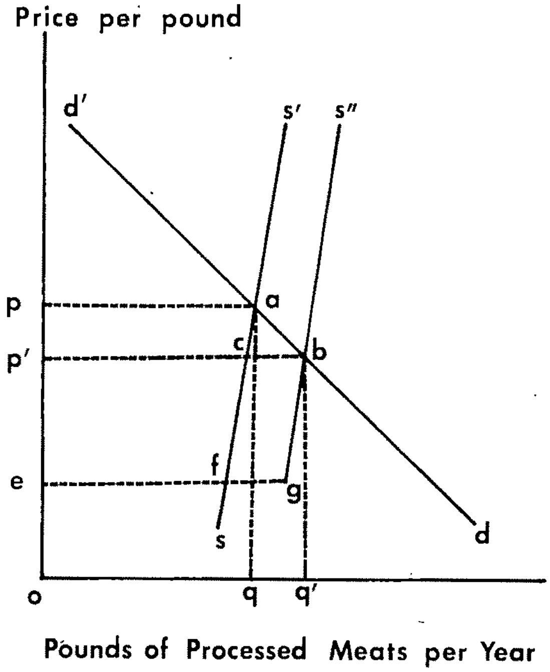

Figure 1. Demand and supply of processed meats

oe represents the minimum price at which producers find it profitable to adopt the technology, regulations relaxing restrictions on MDM use would lead to an increase in the quantity of processed meats supplied at prices above this level, but no change for lower prices. This increase in the supply of processed meats to *sfgs''* would be accompanied by a reduction in the price of processed meats from *p* to *p'*, and an increase in the quantity traded from *q* to *q'*. These price and quantity changes induced by the use of MDM in processed meats result in an increase in the economic welfare of consumers that is measured by area *p'pab*. Part of this gain to consumers is a transfer from producers whose welfare is reduced by an amount measured by area *p'pac*. This transfer from producers is at least partially offset by the welfare gain to producers measured by the area *bcfg*. The net welfare change for society (producers and consumers) is measured by area *bcfg* plus area *abc*. This area represents the net economic welfare gain to society if the use of MDM in processed meats is permitted, or conversely, the net loss in society's economic welfare if MDM use is restricted.

Secondary Effects

The secondary impact of the technology depends on the cross-price elasticities of supply and demand between table cuts and processed meats. As the price of processed meats falls relative to the price of table cuts, the demand for table cuts may decrease in the supply (technical constraints permitting) increase. While the net effect on the equilibrium quantity of table cuts is uncertain, the price of table cuts is expected to fall.

An Empirical Model

In order to estimate the sum of the small individual net benefits associated with mechanically deboning red meats, parameters of the hypothesized demand and supply relations for table and processed meats were estimated along with the appropriate own and cross-price elasticities. The demand for each type of meat was specified as a function of its own price, the prices of related goods, income, and population. The supply of each type of meat was specified as a function of its own price, the prices of related goods, the levels of inputs considered fixed for any production period, and the prices of any inputs whose level of use may be varied during the production period. The coefficients of a number of these explanatory variables were found to be not statistically different from zero, and these variables were subsequently dropped from the model.

Estimation

Series of monthly retail price-quantity data were constructed and used to estimate the parameters of the eight supply and demand equations that evolve from the theoretical analysis above.[3] Because the eight structural demand and supply equations are interdependent and each contains at least two endogenous variables, own price and quantity, the parameters of the over-identified system of equations were estimated using three-stage least squares (3SLS). The 3SLS-estimated equations, as

[3] Monthly price series for table and processed meats from 1970 to 1976 were constructed from the retail meat prices of individual retail cuts published by the Bureau of Labor Statistics and from unpublished USDA data. The prices of individual retail cuts were weighted by their market basket shares to form retail price series for table and processed beef and pork (Duewer, 1969). Monthly total civilian consumption of beef and pork was computed from figures reported in annual supplements of the USDA's *Livestock and Meat Statistics*. After conversion from carcass to retail weight basis, the data on beef and pork consumption were each disaggregated into two components, table cuts and processed meats, using share estimates obtained from USDA consumption surveys which were consistent with the market basket shares used in constructing the price series. Complete data used in this study are available in McNiel.

well as ordinary least squares (OLS) estimates obtained from preliminary investigations, are reported in table 1.

In general, the estimated results are consistent with the priori theoretical analysis developed above. All coefficients have the signs

QTB—Quantity of table beef	*PTB*—Price of table beef
QPB—Quantity of processed beef	*PPB*—Price of processed beef
QTP—Quantity of table pork	*PTP*—Price of table pork
QPP—Quantity of processed pork	*PPP*—Price of processed pork

Exogenous variables

CCS—Commercial cattle slaughter	*POP*—Population
CHS—Commercial hog slaughter	*SC*—Steer-corn price ratio, lagged one year
PI—Personal income	

Note: Standard errors are in parentheses. One asterisk implies significance at the 90% level; two, the 95% level; and three, the 99% level.

economic theory would lead us to anticipate.[4] Standard errors of the 3SLS coefficients are relatively low, except for the coefficient of the price of processed beef (*PPB*) in the demand for table pork equation, and the coefficient of the price of table pork (*PTP*) in the supply of processed pork equation. Because economic theory supports the signs of these coefficients, the variables were retained for purposes of simulating the indirect effects of alternative MDM regulations in the next section.

On the supply side of the model, cross-price effects between table and processed meat of the same species were detected only in the equations for processed beef and pork, and not in supply equations for table beef and pork. No cross-species price effects were detected in any of the estimated supply equations. This may indicate that most of the discretionary supply decisions already have been made at the farm or processing levels in an earlier time period and that the retailer's ability to alter the relative quantities in which table and processed meats of a particular species are marketed (in response to relative price changes) is limited by carcass conformation and decisions made at the processor level. On the demand side, one might expect consumers to make substitutions not only between table and processed meats of the same species, but also between species. This expectation is borne out in the estimated demand equations. The demand for processed beef, for example, is found to depend on the price of processed pork (*PPP*) as well as the price of processed beef (*PPB*). Similar cross-species price effects are found in the other three demand equations as well, but none capture all of the hypothesized cross-price effects.

Elasticities

Table 2 summarizes the retail demand and supply elasticities with respect to the price variables, calculated at the mean using the 3SLS coefficients. Both the own and cross price elasticities of demand and supply are reported when available from the estimated model.

The demand for table beef was found to be more own-price elastic than the demand for processed beef. These relative magnitudes are generally consistent with those reported by Hunt and Houck as opposed to those reported by Langemeier-Thompsons, see table 3. Comparisons of the actual magnitudes of these elasticities may be rather tenuous because of differences in the data series, time periods, and number of submarkets considered in the models from which they are estimated. In the case of pork, the relative magnitudes of the demand elasticities for table and processed pork are reversed. With the exception of Duewer's estimates for eight retail pork cuts, no comparison estimates of the elasticities of demand for table and processed pork were found in other studies.

The estimated supply elasticities are all very small. This is consistent with the fact that meat is highly perishable and has a limited

[4] The positive quantity-axis intercepts in the estimated supply equations are the necessary result for any linear supply curve which is price inelastic. As price approaches zero, the result becomes absurd. However, as the text shows, the quantity supplied at very low prices (below *oe* in fig. 1) has no effect on the analysis of welfare changes.

Table 2. Summary of Estimated Retail Demand and Supply Elasticities

	Elasticity of	
	Demand	Supply
Table beef		
Price of table beef	−1.72	.05
Price of table pork	.64	
Processed beef		
Price of processed beef	− .63	.36
Price of processed pork	.54	
Price of table beef		−.36
Table pork		
Price of table pork	− .86	.05
Price of processed beef	.03	
Processed pork		
Price of processed pork	−1.19	.10
Price of processed beef	.24	
Price of table pork		−.01

Note: Means are $QTB = 910.7$ million pounds, $QPB = 587.9$ million pounds, $QTP = 798.6$ million pounds, $QPP = 230.7$ million pounds, $PTB = 140.6¢$ per pound, $PPB = 81.7¢$ per pound, $PTP = 106.9¢$ per pound, and $PPP = 85.2¢$ per pound.

Table 3. Comparison of Selected Supply and Demand Elasticities for Table and Processed Beef

Own Price Elasticities	This Study	Hunt	Houck	Langemeier-Thompson
Table beef				
Demand	−1.72	−2.03	−1.156	− .978
Supply	.05	.156		.232
Processed beef				
Demand	− .63	−1.35	− .850	−1.243
Supply	.36	.332		− .552

shelf life. Once the livestock producer makes the decision to market the animal, the wholesaler and retailer have little short-run discretion for increasing or reducing the quantity of meat supplied in response to variations in retail prices. The relatively higher supply elasticities for processed beef and pork than for table beef and pork are consistent with the longer shelf life and less restrictive technical constraints on the production of processed meat products—table cuts can be completely converted into processed meats, in response to relative price changes, but the reverse is not technically feasible.

Policy Analysis

The equations presented in table 1 were used to simulate the price and quantity effects of alternative regulations regarding the use of MDM in processed meat products. Prices and quantities associated with a ban were compared with prices and quantities associated with two other alternative policies: the existing policy which would allow a maximum of 20% MDM as an ingredient in all processed meats except ground beef and pork, and a variant which would allow all MDM economically recoverable by existing technology to be used in processed meat products. Information on the minimum price at which the technology would be adopted (*oe* in fig. 1) was collected in a survey of eight large meat packers and processors. This price was assumed to reflect the cost of recovering MDM.

Price-Quantity Effects

The prices and quantities associated with a ban on the use of MDM for human consumption were derived directly from the model which was estimated using data that were generated when use of MDM for human consumption was banned. The prices and quantities were associated with the two alternative MDM policies were simulated by shifting the supply functions for processed beef and pork to account for the addition of MDM to the supply of processed meats. The exogenous supply shifts assumed in simulating each alternative (*fg* in fig. 1) are explained below.

The first alternative approximates the current USDA regulations in that it does not allow MDM to be used in fresh ground beef and pork. Therefore, the supplies of processed beef and pork were each shifted to the right by 20% of the amount of meat consumed in processed form, excluding ground beef and pork; on average in 1976, this implies a supply shift of 9,850 thousand pounds per month for processed beef, and 4,433 thousand pounds per month for processed pork.

The second alternative policy simulated was designed to illustrate what is feasible under a free market policy if red meat producers are allowed to utilize all the MDM they can recover economically, given the present state of the mechanical deboning technology. Industry tests reported by Field indicate that an additional eight to sixteen pounds of MDM per beef carcass and three to six pounds of MDM per pork carcass could be recovered economically, given present technology. With an assumed MDM recovery of twelve pounds per beef carcass, four pounds per pork carcass, and average annual beef and pork slaughter of 40 million head and 80 million head, respectively, processed beef supplies could be increased by 40,000 thousand pounds per month and processed pork supplies by 26,667 thousand pounds per month. These supply shifts for processed beef and pork were utilized in the free market simulation.

The monthly endogenous results from comparing these two simulations with the simulation of the conditions associated with a ban on the use of MDM in products for human consumption were exaggerated for the year 1976, and are summarized in table 4. The results indicate an increase in the quantity of processed meats traded, a decrease in the quantity of table meats traded, and lower prices for both table and processed meats. The magnitude of the price-quantity change varies considerably with the particular MDM policy simulated. The indirect effects in the markets for table beef and pork are relatively small in comparison to the direct effects in the markets for processed beef and pork. Examination of the results of these simulations confirms the a priori economic analysis of the direct effects of mechanical deboning presented above, and also provides answers to some of the theoretical uncertainties about the indirect effects of the technology.

One indication of the direct cost to society of the existing MDM regulations may be obtained by comparing the results associated with the two policies. This comparison implies that existing regulations, which prohibit the use of MDM as an ingredient in fresh ground

Table 4. Summary of Price, Quantity, and Welfare Effects Associated with Alternative MDM Regulations

Simulations for 1976 of the Change in the	Maximum Use of 20% MDM in Processed Meats, Excluding Ground Meat	Use of ALL MDM Economically Recoverable by Existing Technology

Consumers and Producers	111	501

[a] Decreased by less than 0.1¢ per pound.

beef and pork, result in higher retail prices to consumers amounting to about 8¢ per pound for both processed beef and pork. This restriction also means smaller quantities of processed meats will be available to consumers: for 1976, about 104 milion fewer pounds of processed beef, and 240 million fewer pounds of processed pork.

Welfare Effects

The welfare effects attending these price and quantity changes were analyzed using the concepts of economic surplus. Following Mishan's suggestion, only the direct welfare effects in the markets for processed beef and pork are analyzed. Indirect changes in economic surplus in the markets for table beef and table pork are "simply the consequence of consumers' bettering themselves by switching from [table meats] to the new lower-priced [processed meats]" (p. 34). The linear demand and supply functions estimated above and utilized to simulate the changes in equilibrium prices and quantities associated with the alternative MDM regulations, allow the welfare effects mentioned in connection with figure 1 to be computed as follows:

Gain to Consumers
$= \text{area } p'pab = (p - p')(q + q')/2,$
Loss to Producers
$= \text{area } p'pac = (p - p')(q + q' - s(/2,$
Gain to Producers
$= \text{area } bcfg = s(p' - e)$, and
Net Change in Social Welfare
$= \text{area } abc + \text{area } bcfg = s(p + p')/2 - s(e),$

where p and q are the original price and quantity assuming MDM is banned; p' and q' are the new price and quantity under alternative simulated regulations allowing varying amounts of MDM to be incorporated in processed meats; s is the horizontal shift in the supply of processed meats associated with each of the alternative regulations; and e is the minimum price at which the technology would be adopted.

From the estimates of the changes in the economic welfare of consumers and producers reported in table 4, it is apparent that consumers stand to gain considerably from policies permitting the use of MDM as an ingredient in processed meat products. Estimates of the annual welfare gain to consumers range from $224 million to $1,110 million for 1976. While producers' welfare is reduced under each of the alternative regulations simulated, increases in the annual net economic welfare of society as a whole ranged from $111 million to $501 million or about 1% to 5% of expenditures for processed meats in 1976. The cost to society of the existing MDM regulations may be estimated by comparing the differences in the changes in economic welfare associated with the two alternative policies. This comparison suggests that the welfare loss to society from existing MDM restrictions amounts to $390 million for 1976, or about 4% of expenditures for processed meat in that year.

Markup Pricing in a Dynamic Model of the Food Industry

Dale M. Heien

This paper presents a dynamic model of farm and retail prices and quantities. Central to the model is the notion that increases in wholesale prices are transmitted to the retail level via markup-type pricing behavior. This behavior is shown to be consistent with firm optimization under the assumption of constant returns to scale and Leontief production technology at the retail level. The markup hypothesis is tested using the Granger-Sims causality tests. Markup-type price relationships are then estimated for twenty-two food commodities.

Key words: disequilibrium, dynamic models, marketing margins, pricing behavior.

Gardner set out the basic determinants of retail and farm level prices in a framework consisting of a six-equation model which determines (for some given commodity) the retail price and quantity, the farm price and quantity, and the price and quantity of other retail inputs (e.g., marketing services). The basic concept employed is a static equilibrium framework which assumes the equality of supply and demand in each of the three markets. This approach is an excellent vehicle of analysis, providing many interesting insights into the determinants of the farm-retail price spread. For scenarios involving time periods where inventory change is small in relation to total demand, equality of a supply and demand is a realistic assumption. Given the presence of auction markets at farm levels and price competition at retail levels, agricultural markets clear quickly and this assumption is often valid. However, as the time period under consideration becomes shorter, disequilibrium becomes more of a factor in these markets. At the heart of the disequilibrium notion is the recognition that time is required for markets to clear. Hence, while being useful for analyzing the determinants of equilibrium values of the endogenous variables, the Gardner analysis has little to say concerning the time path from one equilibrium point to another. The purpose of this paper is to put forth a theory of food price determination which is consistent with the static model, but which goes beyond it and attempts to describe the dynamics of the sector.

The author would like to thank Robert Crandall, M. Edwin Ireland, and the *Journal* referees for helpful comments.

A Theory of Food Price Determination

The theory of price determination outlined here includes retail, wholesale, and farm levels. Letting uppercase letters represent quantities and lowercase letters represent their respective prices, the retail demand for any given food item is

$$R^d = h_1(r, y),$$

where R^d is retail quantity demanded, r is retail price, and y represents (exogenous) factors such as income. The retail supply function, which is the reduced form of the maximized production function, is

$$R^s = h_2(r, w, z),$$

where R^s is quantity supplied, w is the wholesale price, and z represents prices of other (exogenous) factor inputs, such as marketing services. Demand at the wholesale level for the food input is a derived demand from the retailer and is one of the set of factor demands which result from the derivation of the supply curve. Symbolically this relation is

$$W^d = h_3(r, w, z),$$

where W^d is the quantity demanded at the

wholesale level (e.g., beef carcasses). The supply by the wholesaler is

$$W^s = h_4(w, f, x),$$

where f is the farm price and x is other wholesaler costs. The demand by the wholesaler for the farm input is

$$F^d = h_5(w, f, x).$$

The demand-supply block of the model is closed by specifying the supply of farm input as

$$F^s = h_6(f).$$

The above model is similar to Gardner's, with the exceptions that the wholesale level has been added and there are no demand and supply relations for other factor inputs. It differs from Gardner's model in that it does not assume the equality of supply and demand in both product and factor markets, i.e., $R^d \neq R^s$, $W^d \neq W^s$, and $F^d \neq F^s$. Observation of inventory levels for many agricultural markets indicates that supply and demand are not continually in balance. Recognition of this imbalance has led researchers (Samuelson, pp. 260–69) to specify price adjustment equations following the excess demand approach, or

$$\begin{aligned} r &= h_7(R^d - R^s), \\ w &= h_8(W^d - W^s), \text{ and} \\ f &= h_9(F^d - F^s). \end{aligned}$$

Specification of the above relations serves to "close" the model in terms of equality of equations and unknowns.[1] However, for some levels of the food distribution system, excess demand relationships such as the above seem inappropriate. This is especially true of the retail level. First, there exists no marketwide agent, such as an auctioneer, to initiate the price changes required to drive the unintended inventory change ($R^d - R^s$) toward zero. Second, given the array of products marketed in a modern supermarket, merely keeping track of inventory of each item for restocking purposes appears to be a substantial task. An operationally more realistic theory is one where store managers apply a markup over costs for each product in order to arrive at a price. This notion of markup pricing is reasonable when viewed from the point of view of a store manager. Price changes at the next stage below may be thought of as "signals" which other managers also receive.[2] Hence, the chance of miscalculating and being the only agent to change price in a different manner is reduced, since all managers receive the same signal. This approach is also consistent with economic theory. First begin by noting that under the assumption of constant returns to scale (assumed also by Gardner) the firm's cost function

$$C = h_{10}(R^s, w, z)$$

can be written as

$$C = h_{10}(w, z)R^s.$$

Hence, marginal cost

$$\frac{\partial C}{\partial R} = h_{10}(w, z),$$

which under competitive conditions equals price, or

$$r = h_{10}(w, z). \tag{1}$$

In the short run, food retailing is perhaps best characterized as requiring constant amounts of each input to produce a unit of output. For each unit of output, inputs are required in "fixed proportions." The production function underlying this notion is the well-known input-output or Leontief production function (see Diewert), which for the food retailer can be written as

$$R = \min\left(\frac{W}{a_1}, \frac{Z}{a_2}\right), \tag{2}$$

which has (for constant returns to scale)

$$C = (a_1w + a_2z)R$$

as a cost function. Hence, under competitive conditions,

$$r = a_1w + a_2z. \tag{3}$$

The associated input demand functions are

$$\begin{aligned} W &= a_1R, \text{ and} \\ Z &= a_2R. \end{aligned}$$

For short-run analysis, when the firm is unable to adjust its fixed technology to changing factor prices, the above analysis is applicable. This would appear to be a realistic description of the retail food store's technology at any given time. The Leontief model implies that the elasticity of substitution (σ) between W

[1] Considerations of other components of demand such as inventory holdings and export demand are intentionally omitted in order to focus on the dynamic price formation relations.

[2] Hence the term "stage of processing" model. For more on this, see Popkin.

and Z is zero. In the long run, when inputs are allowed to vary, this assumption is unrealistic. Various substitutions occur as stores become more capital intensive, products are packaged differently, etc. A nonzero, but constant, elasticity of substitution between inputs can be modeled with the constant elasticity of substitution (CES) production function,

$$R = \gamma[\beta W^{-\rho} + (1 - \beta)Z^{-\rho}]^{-\frac{1}{\rho}},$$

which yields the price function,

$$r = \{(\beta/w)^{\sigma}w + [(1 - \beta)/z]^{\sigma}z\}^{\frac{1}{\sigma}},$$

and input demand functions

$$W = g_1\left(\frac{r}{w}\right)^{\sigma}R, \text{ and}$$

$$Z = g_2\left(\frac{r}{z}\right)^{\sigma}R,$$

where $\sigma = \dfrac{1}{1 + \rho}$, $g_1 = \gamma^{-\rho}\beta$, and $g_2 = \gamma^{-\rho}$ $(1 - \beta)$. Assuming that the Leontief technology is "set in place" at some past time (denoted by o), (3) becomes

$$r = a_{1o}w + a_{2o}z, \text{ where}$$

$$a_{1o} = g_1\left(\frac{r_o}{w_o}\right)^{\sigma} \text{and } a_{2o} = g_2\left(\frac{r_o}{z_o}\right)^{\sigma}.$$

If it is assumed that σ is relatively low, then $\left(\dfrac{r_o}{w_o}\right)^{\sigma} \simeq 1$ and $\left(\dfrac{r_o}{z_o}\right)^{\sigma} \simeq 1$. Hence,

$$r \simeq g_1w + g_2z = \left(\frac{\beta}{\gamma}\right)w \quad w + \frac{(1 - \beta)}{\gamma}z.$$

It should be noted that relationships such as (3) could be a result (in an *ex post* accounting sense) as opposed to a behavioral relationship in the model just described. For example, if all markets cleared instantaneously (i.e., if $R^s = R^d$, $W^s = W^d$, and $F^s = F^d$—the Gardner case) and if the production technology were described by (2), then prices will be given by (3) identically. What remains to be done now is to describe how relations such as (3) may be employed as a consistent pricing rule in a disequilibrium model where time is required to make adjustments.

The first step in the development of such a model is the recognition that (1), or for the specific fixed proportions example, (3), is in fact the supply relationship. Under constant returns to scale, marginal cost is a constant over all ranges of output. That (1) is the supply curve can be seen by considering the nonconstant returns-to-scale case. For a Leontief cost function with returns to scale equal to v,

$$C = (a_1w + a_2z)R^v,$$

we have

$$\frac{\partial C}{\partial R} = v(a_1w + a_2z)R^{v-1} = r.$$

The resulting supply curve is

(4) $$R^s = [r(a_1w + a_2z)^{-1}]^{(v-1)^{-1}}.$$

If $v = 1$, (3) results. Hence, rather than setting the supply of output, as they would under (4), firms with CRTS set price.

Given that (3) is an optimal pricing policy for firms with a Leontief technology and CRTS, how should a market model incorporating disequilibrium be closed? The answer lies in the treatment of inventory policy. Consider the following simplified two-level market model where production at the retail level is governed by[3]

$$R = \min\left(\frac{F}{a_1}, \frac{Z}{a_2}\right), \text{ and, therefore,}$$

(5) $$r_t = a_1f_t + a_2z_t,\text{[4] and}$$

(6) $$F_t^d = a_1R_t^s \qquad a_1 > 0.$$

Retail demand is given by

(7) $$R_t^d = \alpha_o + \alpha_1r_t \qquad a_1 < 0,$$

and farm level supply is

(8) $$F_t^s = \gamma_0 + \gamma_1f_t \qquad \gamma_1 > 0.\text{[5]}$$

Prices at the farm level are instantaneously determined by excess demand,

(9) $$\Delta f_t = \beta_o(F_t^d - F_t^s) \qquad \beta_o > 0.$$

With retail price given by (5), the remaining variable to be controlled by the retailer is the quantity supplied in period t, or R_t^s. Since demand may shift (a change in α_o), the firm cannot predict demand with certainty. One useful rule is to set the current period's supply equal to the last period's demand, or

[3] The wholesale level has been deleted for ease of exposition.

[4] We note in passing that for many agricultural commodities, $a_1 \simeq 1.0$. Hence, the elasticity of retail prices with respect to farm price is f/r or the farm-retail price ratio. The a_i's are actually the physical units of farm product needed to produce one retail unit of the product. These requirements are in fact the much-publicized farm equivalents. See Brandow.

[5] For some livestock products it has been shown that $\gamma_1 < 0$ in the short run. However, this occurs when f is an expectational variable—a situation not treated here.

(10) $$R_t^s = R_{t-1}^d.$$

This rule has definite implications for inventory policy. The market described by this model operates in the following manner. Given some shift in demand at retail level, inventories will be depleted more than expected, but retail and farm price will remain unchanged. At the start of the next period, inventories will be increased through the rule given by (10). This increase in R^s will be transmitted to the farm level through (6), and farm and then retail prices will increase in view of (9) and (5). The increase in retail price will tend to restrict retail demand, setting the scene for a downward adjustment of R^s in the next period. This process will continue for several periods until prices and quantities reach their new equilibrium values—assuming that the solution is stable. In order to test the stability of the above model, begin by noting that the six-equation model given by (5)–(10) can be reduced to a simultaneous system of second-order difference equations,

(11) $$r_t = a_1k_o + a_1k_1r_{t-1} + a_1k_2f_{t-1} + a_2z_t, \text{ and}$$

(12) $$f_t = k_o + k_1r_{t-1} + k_2f_{t-1}, \text{ where}$$

(13) $$k_o = (\beta_oa_1\alpha_o - \beta_o\gamma_o)k_2,$$

(14) $$k_1 = (\beta_o\alpha_1a_1)k_2, \text{ and}$$

(15) $$k_2 = (1 + \beta_o\gamma_1)^{-1}.$$

The solution will be stable if the modulus of the characteristic equation of (11) and (12), given by

(16) $$\lambda^2 + \lambda(-k_1a_1 - k_2) = 0$$

lies in the unit circle. The two roots of (16) are

$$\lambda_1 = 0$$
$$\lambda_2 = k_1a_1 + k_2.$$

Using (14) and (15),

(17) $$\lambda_2 = (1 + a_1^2\beta_o\alpha_1)(1 + \beta_o\gamma_1) < 1$$

for the parameter restrictions given above. Hence, the system will be stable if $\lambda_2 > -1$. An exact statement is not possible. However, writing (17) as

$$\lambda_2 = \left(\frac{1}{\beta_o} + a_1^2\alpha_1\right)\left(\frac{1}{\beta_o} + \gamma_1\right)^{-1},$$

it can be shown that if $\left|\frac{1}{\beta_o}\right| > a_1^2\alpha_1$ and $\left|\frac{1}{\beta_o}\right| > \gamma_1$, $\lambda_2 > -1$. Intuition suggests that $\frac{1}{\beta_o}$ will be large relative to $a_1^2\alpha_1$ and γ_1. Hence, the model can give rise to both damped and explosive oscillatory growth as well as convergent growth. Only divergent growth is ruled out. The model is more general in this sense than the classic Cobweb model which permits only damped and explosive oscillatory behavior. However, the main point of the above exercise is to demonstrate that the model given by (5)–(10) can give rise to stable solutions and that for these stable solutions the optimal pricing rule given by (5) will hold. The remainder of the paper is devoted to an empirical test of one component of the above theory—the markup pricing rule given by (3). This is not meant to imply that the other behavioral relations are not important. However, extensive empirical analyses have been undertaken on retail food demand and farm supply. While empirical tests of the inventory rule would be desirable, it is not clear that the available data will support such a test.

Before passing on to the tests, it should be noted that the above analysis is useful in interpreting several results derived by Gardner with respect to markup pricing. First, it can be shown that all CRTS production functions will yield price relationships of the form

$$r = b_1f + b_2z, \text{ where}$$
$$b_1 = h_{10}^f(f, z), \text{ and}$$
$$b_2 = h_{10}^z(f, z).$$

The above can be proved easily. First, remembering that for CRTS

(18) $$C = h_{10}(R, f, z) = h_{10}(f, z)R.$$

Because the definition of the cost function is

$$C = Ff + Zz,$$

and from Shephard's lemma (Diewert, pp. 495–96),

$$F = \frac{\partial C}{\partial f}, \text{ and}$$

$$Z = \frac{\partial C}{\partial z},$$

(18) can be written as

$$C = [fh_{10}^f(f, z) + zh_{10}^z(f, z)]R.$$

Hence,

$$\frac{\partial C}{\partial R} = r = b_1f + b_2z, \text{ where}$$

$$b_1 = h_{10}^f(f, z), \text{ and}$$
$$b_2 = h_{10}^z(f, z).$$

For dynamic models where b_1 and b_2 are "set in place" by past prices, pricing rules will be of the fixed markup variety at any given point in time, regardless of the *ex ante* production function. Hence, markup pricing will yield fully consistent results in a theoretical sense for dynamic models with CRTS and (at any given time) fixed technology. Second, Gardner makes the point that "no simple markup pricing rule . . . can in general accurately depict the relationship between farm and retail price" (Gardner, p. 406). The validity of this statement is a direct result of the fact that b_1 and b_2 above are endogenous to the Gardner model and will change differentially depending on how f and z change as a result of various shifts in their basic determinants. This result shows at once the strengths and weaknesses of a static model. To allow changes in technology (as a result of basic supply and demand shifts) to explain changes in margins and price transmission is an extremely valuable tool. When employing this tool, it must be borne in mind that one is considering a time period long enough for these price-induced technological changes to occur.[6] Hence, the stability of the coefficients in (3) can provide clues as to the proper period of time for use of a static model.

Testing for Causal Direction

The general model presented above relies on the notion that changes in prices at the retail level are caused by changes in prices at the wholesale level. For some commodities, this notion could also be extended to the farm-wholesale stage. However, problems in obtaining independent farm and wholesale price measures for highly integrated industries such as poultry and eggs and processed vegetables, extreme seasonality, and the presence of speculative inventory behavior require that a detailed, industry-by-industry analysis be conducted to test the price markup model at the wholesale level. At the retail level this behavior is much more plausible mainly for the reasons given above. The notion of one buyer (the retail outlet) for all commodities, the ability of that buyer to set price (i.e., absence of auction markets), and the myriad of products to be priced lend credence to the rule. Hence, tests will be conducted at the retail stage only for the model given by (3), which in effect says that wholesale prices and other input prices cause retail prices.

The notion of causality has long plagued empirical economic analysis. Problems of "mutual trends" or third factor causality have made econometricians reluctant to draw causal conclusions based on regression results. Some attempts have been made to "detrend" the data or deal in percentage changes, but in the main, the question of causality is decided a priori, based on theoretical considerations. Given the nonexperimental manner in which economic data are obtained and the aforementioned problems with time-series data, this theoretical approach is justified. Recently, Sims, utilizing a concept of causality from time-series analysis developed by Granger, has devised a method to test for causal direction.[7] The test proceeds by first filtering the series.[8] The filtered values of the original series, X and Y, are referred to as $\bar{X}$ and $\bar{Y}$. A regression, of the form

$$\begin{aligned}\bar{Y} = \beta_0 + \beta_1\bar{X}_{t+4} + \ldots + \beta_4\bar{X}_{t+1} \\ + \beta_5\bar{X}_t + \beta_6\bar{X}_{t-1} + \ldots + \beta_{13}\bar{X}_{t-8} \\ + \beta_{14}D_1 + \ldots + \beta_{24}D_{11} + \beta_{25}t + u_t,\end{aligned}$$

is performed where the D's represent monthly seasonal dummies. The coefficients $\beta_1, \ldots, \beta_4$ are called future coefficients. Significance tests are then made on the future coefficients from each regression. Table 1 summarizes the various possible combinations and the implications of each. The results of applying the causality tests to monthly data from 1960-1 to 1976-12 for twenty-three food items are summarized in table 2.

Table 1. Conditions for Direction of Causality

Regression	Future Coefficients	Direction
$\bar{Y}$ on $\bar{X}$	Significant	Unidirectional
$\bar{X}$ on $\bar{Y}$	Not Significant	from Y to X
$\bar{Y}$ on $\bar{X}$	Not Significant	Unidirectional
$\bar{X}$ on $\bar{Y}$	Significant	from X to Y
$\bar{Y}$ on $\bar{X}$	Significant	Bidirectional
$\bar{X}$ on $\bar{Y}$	Significant	between X and Y
$\bar{Y}$ on $\bar{X}$	Not Significant	Independence
$\bar{X}$ on $\bar{Y}$	Not Significant	between X and Y

[6] This is in no way meant to imply that Gardner was not fully aware of this requirement.

[7] In actuality there are several tests based on the Granger notion. These tests are discussed fully in Feige and Pearce. The tests employed here follow Sims.

[8] The filter weights used for this study were $\bar{Y}_t = \ln Y_t - 1.51 \ln Y_{t-1} + .562 \ln Y_{t-2}$. The first difference filter $\bar{Y}_t = \ln Y_t - \ln Y_{t-1}$ was also used. The results were invariant.

Table 2. Classification of Test Results

Condition	Wholesale-Retail
Unidirectional-upward	beef, oranges, frozen orange juice, rice, salad oil, margarine, vegetable shortening, sugar, pork, potatoes, frozen french fries, bread, chocolate bars (57%)
Unidirectional-downward	milk, soft drinks (9%)
Bidirectional-causality	butter, fresh orange juice, canned tomatoes (13%)
Independence	broilers, eggs, apples, tomatoes, lettuce (21%)

Note: Significance tests were based on t-values of 1.5 or greater, which for this sample size correspond to a 94% confidence interval. The percentage figures in parentheses represent the proportion of the total number of commodities in each class.

With the exception of soft drinks and chocolate bars, the food items in table 2 were selected from the U.S. Department of Agriculture (USDA) market basket. The retail prices are USDA data while the wholesale price indexes are from the Bureau of Labor Statistics. Broadly speaking, the results in table 2 support the theoretical arguments given above concerning the direction of causality from wholesale to retail. There are, however, important exceptions. The proportion of items displaying independence is larger than would be expected. However, this is consistent with recent findings by Pierce in an extensive examination of monetary variables. Pierce ascribed the large degree of independence mainly to lack of sufficient variability in the data or lack of controlled experimentation. Also, the existence of control strategies such as price supports tends to obscure the lag distribution pattern. In interpreting the above results, the reader should be cautioned that considerable controversy surrounds these causality tests. These problems center around two areas: the choice of a filter and the choice of the test itself. As noted above, several alternative testing procedures exist as empirical implementations of the Granger definition. Tests by Feige and Pearce using all three tests on the money-income hypothesis found the results sensitive to both the test procedure and to the filter used. Choice of a proper filter has long plagued spectral analysis and the same appears true for these tests. Nonetheless, the results are in accord with the theoretical development above in section 1 and on that basis tend to reinforce those considerations.

Wholesale-Retail Price Relationships

The notion of the price linkage between the wholesale and retail levels has thus far been confined to the specification given by (3). However, our empirical tests are based on monthly data and hence, for reasons given below, it may be useful to specify retail prices as a distributed lag in wholesale prices, or

$$(19)\quad r_t = \beta_0 + \beta_1 w_t + \ldots + \beta_k w_{t-k} + \beta_1 ulc_t + \beta_m ur_t,$$

where r is retail price, w is wholesale price, ulc is unit labor costs for retail food stores, and ur is the unemployment rate.[9] The distributed lag in w is specified to account for the notion that store managers may wish to use a "smoothed" value of w to avoid changing prices. Changing price is not a problem for perishables, but for items with a long shelf life, price changing is costly both in terms of time to put on new labels and in goodwill lost. Also, it may be true for some items that data collection times differ. Hence, for example, the January beef prices will represent prices observed at different days in the month. Unit labor costs, instead of the wage rate, were used for similar reasons. Unit labor cost data displayed a smoother time path than wage rates and in order to conserve degrees of freedom, ulc was used as opposed to a distributed lag in wage rates.[10] Also included was the unemployment rate as a measure of firms' normal unit rate of return. The results of fitting the model given by (19) to monthly data for the twenty-two commodities are given in appendix A. The relations typically displayed considerable autocorrelation. A correlation was made using Durbin's method. The results of appendix A are self-evident, with the exception of column (10)—the asymmetry test. The asymmetry hypothesis tests whether retailers treat increases in wholesale prices in a manner differ-

[9] Although the fixed coefficient theory does not indicate a constant term (β_0), one is included due to problems in estimating regressions without intercepts. On this problem see Gillingham and Heien.

[10] Wage rates, in fact, dominate the movement in unit labor costs for retail stores. Regressions were run with wage rates and the results were quite similar. Also, regressions with a six-month moving average of wage rate and unit labor costs showed virtually no difference.

ent than decreases. More precisely, it is often hypothesized that increases in prices are passed on fully, while decreases are not, mainly so that other costs (wages) can be "worked in." Fortunately, the methodology for testing such a hypothesis has been fully developed. In a study of supply response, Tweeten and Quance estimated an irreversible supply relation (i.e., a supply with asymmetrical price response) using dummy variables. In subsequent notes, Wolffram and Houck pointed out that their approach was unduly restrictive in that only the slopes and not the intercepts were allowed to be different. In order to implement this test at the retail level, two new variables (w_1 and w_2), representing upward and downward movements in the wholesale price, respectively, were computed. A regression of the form

$$r = \beta_0 + \beta_1 w_1 + \beta_2 w_2 + \beta_3 ulc + \beta_4 ur$$

was performed. The coefficient β_1 gives the effect on retail prices when wholesale prices are rising, while β_2 measures the effect when wholesale prices are falling. The hypothesis to be tested then reduces to the equality of $\hat{\beta}_1$ and $\hat{\beta}_2$, or H: $\hat{\beta}_1 - \hat{\beta}_2 = 0$. The statistic for this t-test is found in the lower half of column (10). Examination of column (10) shows that in twelve of the twenty-two cases, the sign was positive. Although $(\beta_1 - \beta_2)$ should be greater than zero if the hypothesis holds, a simple examination of signs indicates it does not. Rejection of the hypothesis is further reinforced by the fact that in only five cases does the t-value have both the correct sign and exceed two standard errors. A structural stability test was performed on each relation to determine whether or not there was a significant change in coefficient values in the 1975-1 to 1976-12 period. Using a test value of 4.0, the hypothesis of structural change was rejected in fifteen out of twenty-two cases. The stability of these parameters lends support to the Leontief-fixed proportions technology concept specified above.

Summary

This paper presents a dynamic theory of food price determination for the farm, wholesale, and retail sectors. The system derives its dynamics from the assumption that supply and demand are not in balance and that this imbalance is the determining factor in causing price changes in auction-type markets. Central to this theory is the notion that changes in retail food prices are caused by changes in prices at lower levels in the marketing chain. These cost changes are transmitted via markup-type-pricing rules which are shown to be consistent with firm optimization behavior under the assumption of constant returns to scale and time-fixity of production coefficients. Solution properties of the model allow for convergent growth and damped and explosive cycles, ruling out only divergent growth. For reasonable parameter values, solutions are stable and convergent growth appears to be the most likely case. The hypothesis of markup pricing at the retail level is tested by applying the Granger-Sims causality tests. Test results show that for the majority of the twenty-two commodities tested, unidirectional causality from wholesale to retail is the rule. Next, empirical price markup relations are estimated using retail price as a distributed lag in wholesale prices and unit labor costs. Additional tests on structural stability and asymmetric pricing are also performed. The relations are structurally stable and the hypothesis of asymmetric pricing behavior is rejected.

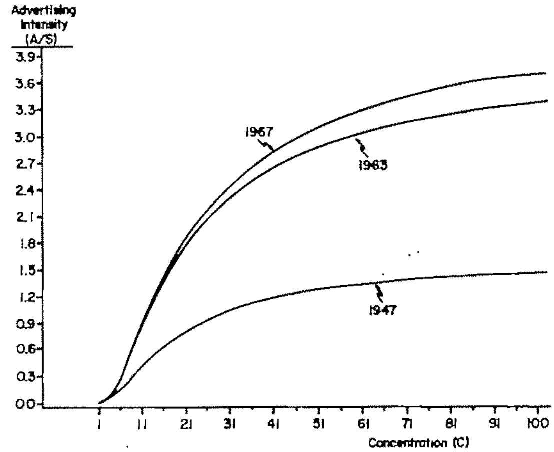

Figure 2. Advertising intensity-concentration relationship for consumer nondurables across time (1947, 1963, 1967)

creases, the advertisng intensity rises rapidly for both goods. Beyond the 20% level very little increase among producer goods industries is evident; whereas, advertising continues to rise rapidly for the consumer goods. The durable category is not shown since the relationship does not differ significantly from that shown in figure 1.

Adjustment over Time

Figure 2 illustrates the adjustments that have taken place since 1947, and the increased use of advertising for each concentration level is most apparent. Advertising intensity has increased and one important consideration is how much increase would have occurred without any change in concentration. Increased intensity with more concentration suggests substitution of nonprice for price competition. Increased intensity over time holding concentration levels fixed does not preclude the substitution for price competition, but it does indicate that greater effort to establish information flows has occurred.

The changing slopes of each response in figure 2 is of special importance in that they clearly show that the effects of structural change on advertising intensity have increased since 1947. The rate of increase in advertising intensity to increases in concentration nearly doubled between 1947–67. While advertising has become more important to concentrated industries, the results still do not totally show how much of this change represented substitution for price competition. A useful extension of the analysis would be to explore an index of price changes among the same industries included in this study.

Figure 3 is useful for depicting the adjustment that has occurred since 1947, holding all concentration levels fixed at their 1947 values. The vertical axis gives the estimated percentage adjustments that would have occurred due to the time alone and is calculated as

$$(3) \quad \frac{(A/S)_{67}}{(A/S)_{47}} - 1 = \exp^{-\left\{\beta_3 + \frac{\alpha_2}{C_{47}}\right\}} - 1,$$

where $C_{47} = C_{67}$ is assumed [see eq. (1)].

Advertising intensity would have declined over time for those industries with concentration under 2%. Whereas for industries having initial concen-

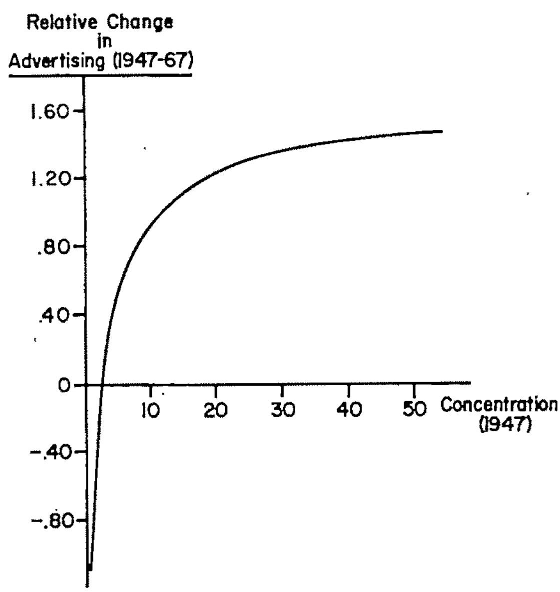

Figure 3. Relative change in advertising intensity from 1947 to 1967 holding concentration levels fixed (see eq. 3)

turing (Ornstein, pp. 74–85). Industries differ within the four-digit classification and, hence, the effect of concentration may vary across industries. Therefore, in addition to the classifications by type and perishability, the concentration parameter may have a random component giving $\alpha_0 + \nu$, where ν is an error term having the traditional properties. The dummy variables were defined such that both β_0 and α_0 represent some average effect, and the differences in type are calculated as some adjustment to this average. The randomness in the concentration coefficient is calculated only for this average and not each parameter in (1). The error in (1) is now $\mu + \nu(1/C)$, and the variance is $\sigma_\mu^2(1 + \rho/C^2)$, letting $\rho = \sigma_\nu^2/\sigma_\mu^2$ (Maddala, p. 390).

Equation (1) is estimated by maximizing the concentration likelihood function over values of ρ and the results are shown in table 2. The random coefficient model adds little to the analysis since the maximum value of the likelihood function occurs when $\rho = 0$. Pooling the data across four-digit concentration levels after explicitly accounting for time, type, and perishability does not create estimation problems that might have been expected initially, given the diverse nature of the industries included in the sample.

The statistical results shown in table 2 are probably the strongest to date in support of the relationship between advertising intensity and concentration. The t-values for α_0 and α_1 show the relationship to be significant at the 99% confidence level. Furthermore, response among consumer industries is statistically different from those producer goods industries. This difference is of particular interest since much of agricultural manufacturing relates to consumer goods in the form of food and kindred products. No statistical difference between durable and nondurable goods is evident. Finally the coefficient of determination shows that 39% of the

variation in advertising intensity has been explained. Other factors, some of which are likely unique to each industry, must be addressed in order to further explain intensity. What is important at this stage in the advertising-concentration dialogue is that the relationship has been established. An alternative to model (1), where substantial concentration could eventually lead to less advertising, has been specified as

$$(2) \qquad \frac{A}{S} = \exp^{(\tau_0+\tau_1/C+\mu)}C^{\tau_2}.$$

If $\tau_2 < 0$ and $\tau_1 < 0$, advertising intensity could both increase and decrease with C. This function has the property that $A/S \geq 0$, whereas many of the polynomial functions reported could yield $A/S < 0$. This model was estimated and the empirical results failed to yield any improvements over those in table 2, thus adding more credence to the asymptotic function (Ornstein, Strickland and Weiss).

Product Classifications

As suggested above, a large number of the nondurable industries relate to food and kindred industries. Attempts, however, explicitly to separate out the advertising intensity relationship for this subset of four-digit industries have not proven significant. Rather, the broad product class of consumer versus producer goods is the most important distinction. This would be expected because buyers of producer goods should be less susceptible to product image created by advertising (Mann, p. 139; Strickland and Weiss, p. 1111). Producer products are purchased in sufficient volume and frequency that the alternatives can be appraised. Also, consumer goods are generally more differentiable. Generally, the number of potential buyers are less for the producer versus consumer goods and, hence, the cost of reaching the buyers of producer goods should be less.

When comparing the effects of concentration on consumer versus producer goods, one would expect intuitively the elasticity of demand to change less among those producer versus consumer goods because the product is judged primarily on its characteristics and less on image. Hence, the significance of α_1 in table 2 seems plausible from a theoretical perspective. We are still left with the issue of what happens to ϵ_a for both product categories. If consumers are more susceptible to the image effect in consumer goods as suggested by Mann, then $\partial\epsilon_a/\partial C$ for consumer goods is likely to exceed that of producer goods and the advertising intensity for consumer goods should exceed that of producer goods.

The relationship between producer and consumer goods is illustrated in figure 1 for the nondurable category. Obviously, advertising plays a small role in the very low concentrated industries regardless of the product category. As concentration in-

Table 1. Hypothesized Effects of Concentration on Advertising Intensity [$\partial(A/S)/\partial C$]

	$\partial\epsilon_a/\partial C$		
$\partial\lvert\epsilon_d\rvert/\partial C$	+	0	–
+	?	–	–
0	+	0	–
–	+	+	?

Note: The signs within the table follow from the relationship where $\partial(A/S)/\partial C = (1/\lvert\epsilon_d\rvert)[\partial\epsilon_a/\partial C - (A/S)(\partial\lvert\epsilon_d\rvert/\partial C)]$, as derived using the Dorfman-Steiner theorem.

The problem with hypothesizing the advertising-concentration relationship is illustrated in table 1, where the alternative signs for $\partial(A/S)/\partial C$ are shown. Given the difficulties in determining the signs from the effects of concentration on ϵ_a and ϵ_d, an alternative would be to estimate directly the relationship between advertising and concentration. The empirical results may then suggest the relative importance of ϵ_a and ϵ_d to the advertising-concentration issue.

Advertising-Concentration Model

The analysis from the above section indicates that the advertising-concentration relationship ultimately will depend on empirical models. To date, mixed results have been reported when estimating the model where $A/S = f(C)$ (Mann, pp. 142–56). While the theoretical problems cannot be compromised, many of the difficulties with previous studies can be related to model misspecification, incompleteness in data classification, and inappropriateness of the estimation techniques. Recent studies by Ornstein have addressed the empirical problems of relating advertising and concentration. His studies show a positive but statistically weak relationship between concentration and advertising. Additional studies by Brush provide support for the validity of the data series developed by Ornstein.

For the present problem, concentration and advertising data are taken from the SIC for four-digit industries. The value of shipments of the top four firms relative to total shipments is used as a measure of concentration and the advertising data from Ornstein's study are used (p. 45). Shepherd provided an adjusted data series for the 1966 four-firm concentration ratios for the purpose of correcting what was believed to be a problem with the data similar to that used by Ornstein. Brush's studies of Ornstein's models using the corrected data led him to conclude that "correction of errors in the official Census concentration ratios has had little effect on the statistical estimation of the advertising concentration relationship . . ." (p. 985). For this reason, the initial data reported by Ornstein will be used. The advertising and concentration levels are measured across industries and the SIC codes are classified according to consumer versus producer goods, and durable versus nondurable goods. Many of the consumer nondurables are food industries. The cross-sectional data of four-digit industries are recorded over the years of 1947, 1963, and 1967.

Both Ornstein's and Strickland and Weiss' models are specified such that the intensity may decline with high levels of concentration. Ornstein's results supporting a declining intensity are statistically weak. Whereas, while Strickland and Weiss' statistical results are strong, there appears to be some difficulty with changes in the signs of their advertising relationship as they change the specification of their model (p. 1116). In the current model, the specification facilitates a nonlinear relationship initially assuming that the effect of concentration at least approaches some upper limit. The alternative where the intensity may decline is considered. The asymptotic function follows as the adjustments in ϵ_a and $\lvert\epsilon_d\rvert$ can be expected to approach limits such that $\lim \partial\epsilon_a/\partial C = 0$ and $\lim \partial\lvert\epsilon_d\rvert/\partial C = 0$.

The response to concentration may differ across industries simply because of the differences in both advertising and price elasticities for particular product categories. Finally, there may be reason to suspect that advertising intensity has increased since 1947 as a partial result from increased availability of advertising media. Each of the adjustments above have been ignored in most model specifications or at least have been treated in separate models.

Using the above arguments, the model specification below can be used to test the advertising-concentration relationship.

$$\frac{A}{S} = \exp^{(\tau_0 + \tau_1/C + \mu)}, \tag{1}$$

where

$\tau_0 = \beta_0 + \beta_1 PRO + \beta_2 DUR + \beta_3 T_1 + \beta_4 T_2$, and
$\tau_1 = \alpha_0 + \alpha_1 PRO + \alpha_2 DUR + \alpha_3 T_1 + \alpha_4 T_2$, and
A/S is the advertising-sales ratio (i.e., $0 \leq A/S \leq 100$);[1] C is the four-digit, SIC industry classification ($0 \leq C \leq 100$); PRO is the type of good (-1, producer; $+1$, consumer); DUR is a perishability measure (-1, durable; $+1$, nondurable); T is year where ($T_1 = 1$, $T_2 = 0$, for 1947; $T_1 = 0$, $T_2 = 1$, for 1963; $T_1 = 0$, $T_2 = 0$, for 1967). Note that τ_0 and τ_1 include the effects of PRO, DUR, and T, and both the level of advertising intensity and the response of advertising intensity to levels of concentration. Finally, the relationship has the asymptotic property where $\lim_{C\to 100} A/S = \exp^{(\tau_0 + .01\tau_1)}$, and the limit will change directly depending on the time and product classifications.

Equation (1) is estimated over a sample of 914 observations drawn from the Census of Manufac-

[1] Advertising was not deflated over the three time periods because both sales and advertising are influenced by inflation and the effects of inflation should be netted out in the intensity ratio.

Revisiting the Advertising-Concentration Issue

Ronald W. Ward and Robert M. Behr

Increases in advertising efforts are reasonably well documented among most U.S. industries (Nelson, p. 43). Yet, the economic controversy relating to the causal linkage between advertising intensity and changing market structures is not settled. Advertising can represent a major barrier to entry by its role in achieving product differentiation. In contrast, advertising may enhance competition with the dissemination of information through competitive advertising. While the advertising issues are varied and complex, this paper will set forth additional empirical evidence showing the relationship between advertising intensity and changing industry structure. In particular, the intensity of advertising across industry levels of concentration will be addressed and reference will be given to the food industries.

Studies suggesting that advertising leads to increased concentration have at the best been mixed (Blair). The argument suggesting that the advertising intensity varies positively (or negatively) with concentration has been slightly more definitive. Schmalensee argued that as concentration increases and profits rise, the marginal unit of sales becomes more profitable and it pays more to advertise to capture these additional sales (Mann, p. 150). Strickland and Weiss developed a simultaneous equation model with one equation relating advertising intensity to concentration where both variables are endogenous. Their analyses show that little bias is evident when the advertising intensity equation is estimated as a single equation in contrast to the simultaneous equation results (p. 1116). Because the primary focus of this analysis is to gain a better understanding of changing advertising intensity, the relationship is estimated in a single equation framework relying on Strickland and Weiss's conclusions as to the degree of bias that may occur.

The basic arguments for concentration influencing advertising intensity are two. (*a*) With increased concentration, firms recognize their rival's advertising reaction curve and will thus decrease their advertising effort on the assumption that it only has a neutralizing effect on the rival's advertising. Or, (*b*) with increased concentration, firms will substitute nonprice competition via advertising for price competition. The second argument implies a positive association between advertising and concentration, while the first argument suggests a negative relationship. These effects in turn lead to the public policy dialogue concerning the net social benefits derived from price versus nonprice competition.

Advertising-Concentration Linkage

Dorfman-Steiner's studies of price and nonprice decisions provide a clear linkage establishing the static optimal advertising decision rule to be related to both price and nonprice decisions (Needham, p. 87; Ward, p. 500). If ϵ_a and ϵ_d are the firm's elasticities of advertising and demand, then $A/S = \epsilon_a/|\epsilon_d|$ according to the static rule where A is advertising expenditures and S is sales.

The current issue is how the advertising intensity (A/S) changes with industry concentration (C) and how concentration influences both ϵ_a and $|\epsilon_d|$. The advertising and concentration relationship obviously is confounded in the effect concentration has on both elasticities. If concentration leads to greater economies of scale to advertising and increased product differentiation (i.e., $\partial\epsilon_a/\partial C > 0$) and a corresponding reduction in substitutes (i.e., $\partial|\epsilon_d|/\partial C < 0$), then it always follows that advertising intensity will increase with concentration. The adjustments in ϵ_a and ϵ_d are not altogether clear, however.

The firm's advertising elasticity further has been shown to be related to the rival's advertising response (Needham, p. 85). Assuming that the industry structure is such that rival response is not apparent, then the arguments for a neutralizing and/or retaliatory advertising response are not relevant. However, as concentration increases anticipated rival response can not go unnoticed.

The concentration-intensity linkage is further confounded when one turns to the effects of concentration on the elasticity of demand. Price elasticity of demand is related to the rival's response, and this response is influenced by the level of concentration. With no rival response it is relatively easy to show that the firm's demand becomes less elastic with increased concentration. If increased rival response to firm price changes is anticipated, advertising will be substituted for price competition. However, as concentration increases, rival impact may be lessened and the need to substitute nonprice for price competition would be reduced.

Ronald W. Ward is a professor and Robert M. Behr is a graduate assistant in the Food and Resource Economics Department, University of Florida.

Florida Agricultural Experimental Station Journal Series No. 1925.

western Canada, the only significant factor is the size of the Canadian crop relative to local demand. After navigation is reopened in the spring, both local production relative to demand and the availability of western feed grains have significant effects. The relative insensitivity of the variable representing western feed grains suggests that Canadian policy affecting western grains is not normally as significant a factor in determining Ontario corn prices as is often perceived in Canada. This inference must, however, be qualified by the difficulties in measurement of the variable and by the coefficients on *D*73 which suggest that events in western Canada are important in extreme circumstances.

That the basis for corn in southwestern Ontario adjusts to local market conditions as theory implies provides some reassurance about the market's pricing performance. However, the analysis does not purport to provide evidence on whether prices are optimum in any sense. From a practical standpoint, the analysis provides information that could be useful to local traders and hedgers in understanding the factors which affect the basis.

Dummy Variables

Dummy variable D72 was included for January through July of crop year 1972 (i.e., calendar year 1973) to account for an inversion in corn futures prices during this period. As a result, U.S. export prices apparently were based on the spot instead of the nearby futures price, and the Ontario basis showed substantial premia over the futures prices.

Dummy variable D73 was included for the months of November through June (except March) of crop year 1973. During that crop year, the Canadian Wheat Board established initial prices for Board grains at high levels. This led to the delivery of most board grains to the Canadian Wheat Board, which then exported them. As a result, there was little movement of western grains to the East and therefore a premium was bid on Canadian corn. In March 1974, when navigation opened, the premium disappeared, reflecting expected U.S. corn imports. However, little U.S. corn was imported until July; so the premium on Canadian corn reappeared from April through June.

Dummy variable D74 was included for July and August of crop year 1974. The 1974 corn crop in Canada was of record size. In the fall, trade sources believed Canada would be in a surplus position and, accordingly, exported a record 10 million bushels early in the crop year. Subsequently, it became apparent that domestic demand for corn had been underestimated and substantial amounts of U.S. corn were imported late in the crop year.

The results in table 1 indicate that the market aberrations each had considerable positive impact on the local basis, as expected.

Sensitivity of Basis Residual to the Explanatory Variables

It is of interest to show the sensitivity of basis to changes in the explanatory variables. While this normally would be done using elasticities, elasticities are of little meaning in this analysis because of the small magnitude of the dependent variables. Instead, the absolute change in basis associated with a 10% change from the mean in each explanatory variable is presented in table 2.

Data in table 2 indicate that basis residual is quite sensitive to most of the variables. Of the eight months for which the ratio variable (*IPOC*) is significant, a 10% change results in 3¢ per bushel or more change in basis in six months. Domestic corn consumption averaged about 110 million bushels per year over this period. Hence, the 10% change in *IPOC* represents approximately 8.5 million bushels in Canadian production.

The basis residual in November and December is quite sensitive to Canadian and U.S. corn production. The greater sensitivity implicit in the U.S. production variable is initially surprising; however, a 10% change in U.S. production is more than five times total Canadian production.

Basis residual for May through July is not particularly sensitive to western feed grain availability. However, during the sixteen years of the analysis, shipments of western feed grains to eastern Canada varied from virtually nil to 1.03 million tons. A change in shipments of 10% from the mean is only 72,000 tons; but year-to-year changes obviously can be far in excess of this.

Conclusions

The analysis suggests that a substantial amount of the variation in the southwestern Ontario basis is explained by variables reflecting local market conditions. During the fall months, the size of the Canadian and U.S. crops is the most important factor. During the winter, when the eastern Canadian market is essentially closed except to relatively costly rail access from the United States and

Table 2. Absolute Change in Basis Associated with a 10% Change in Each Explanatory Variable

Month	Mean of Basis Residual	Change in Basis from a 10% Change in:[a]			
		IPOC	*CCP*	*USCP*	*WFGA*
		($/bu)

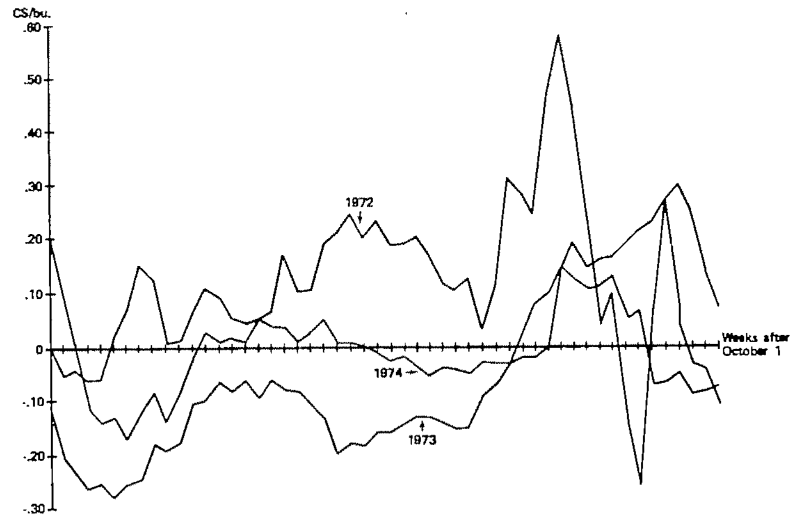
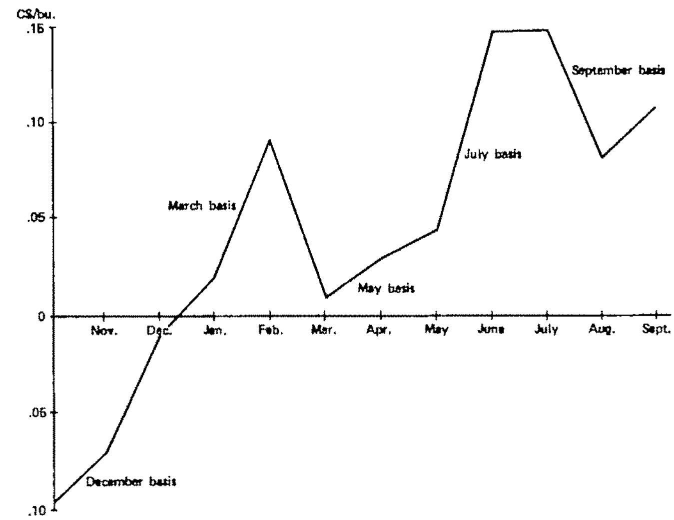
November	−.077		−.027	.072	
December	−.044		−.020	.050	
January	−.022	−.035			
February	.099	−.037			
March	−.005	−.033			
April	.005	−.031			
May	.026	−.021			−.011
June	.071	−.016			−.013
July	.107	−.034			−.010

[a] Means of the explanatory variables are: *IPOC* = .76 = ratio of Canadian production to consumption; *CCP* = .86 = 86 mil. bu.; *USCP* = 5.7 bil. bu.; *WFGA* = .72 = 720 thousand tonnes.



Note: See footnote [2] for explanation of figure.

Figure 1. Weekly basis for corn, Chatham, Ontario, crop years Oct.–Sept. 1972, 1974, 1975



Note: See footnote [2] for explanation of figure.

Figure 2. Monthly corn basis, averaged over crop years 1971–75, Chatham, Ontario

services. Hence, the size of the U.S. crop is a proxy for the demand for these services. Both factors suggest that the size of the U.S. corn crop would be related directly to the Ontario basis during the fall.

Again, the analysis confirms the expectation as indicated by the coefficients for November and December in table 1.

Western Feed Grain Availability

Western feed grain availability is included as a proxy for Canadian Wheat Board and federal feed grain pricing policy. These policies have changed often and markedly during recent years and are therefore both unquantifiable and unpredictable. However, a measure of availability is included on the ground that competition from western feed grains should be expected to affect the eastern corn basis. Availability was measured initially as stocks of western feed grains in lakehead and eastern elevators. However, in initial runs, this variable was found to carry no statistical significance. This is likely because the data do not separate stocks intended for domestic and export markets.

As an alternative, actual movements of western feed grains to the domestic eastern market were used in the analysis. This variable is expected to be related inversely to the basis. The expectation is confirmed by the coefficients on the variable from May onward in table 1.

		(−1.09)			(−2.31)	(4.31)	(2.48)			
July	.514	−.441			−.142	.292		.166	.76	.061
		(−2.64)			(−2.22)	(4.68)		(2.49)		

Note: Units in which the explanatory variables are measured are: *IPOC*, ratio of Eastern Canadian production to Eastern Canadian consumption with 1 occurring when the two are equal; *CCP*, 1 = 100 million bu.; *USCP*, 1 = 1 billion bu.; *WFGA*, 1 = 1 million tonnes.

these areas. The latter is relatively costly and tends to result in Ontario prices being bid up relative to the futures price.

Great Lake-St. Lawrence shipping is opened during March or April, resulting again in increased competition for the eastern Canadian market and a narrower basis. During the late spring and summer, Ontario prices have tended to increase relative to the futures price because Ontario's crop has not been sufficiently large to meet eastern Canada's demand during these months.

The resulting seasonal basis pattern is apparent in figure 2, which contains the average nearby Chatham basis for each month of crop years 1971–75. To account for this seasonality, and on the hypothesis that different factors affect the basis in different months, a separate equation was estimated for each month of the crop year. The results in table 1 tend to support this hypothesis. (As in figure 1, basis in figure 2 is calculated from the nearby future and is adjusted for exchange rates.)

Ratio of Eastern Canadian Corn Production to Consumption

This variable was included to account for competition in the eastern Canadian market between domestic and U.S. corn, as discussed in the previous section. As the ratio approaches or exceeds unity, domestic and imported corn would compete east of Montreal or on the export market and the Chatham basis would be bid down for the reasons explained earlier. Thus, the variable should be related inversely to the basis throughout the crop year.

The results are as expected. The ratio is significant in all months except November and December when harvest variables explain much of the basis variation (see below).

Canadian Corn Production

This variable was included because of the expected relationship between the size of the crop and storage charges in Ontario. The larger the crop, the greater the demand for storage; hence, the local basis would be expected to fall to cover increased storage costs.

The results are consistent with the expectation. The Canadian crop is a significant variable during the harvest period as would be anticipated because this is the period when demand for storage is greatest.

U.S. Corn Production

U.S. corn production is included for two reasons. First, the size of the crop could be a determinant of short hedging pressure at harvest time. A large U.S. crop would place downward pressure on futures prices. Second, a large U.S. crop would motivate shipping more corn through the Great Lakes-St. Lawrence system in the fall before the close of navigation. This, in turn, would increase the demand for transport and handling services during this period, thereby increasing the costs of these

Notes

The Impact of Beef By-Product Exports on Live Cattle Prices

Martin Blake and Tom Clevenger

Since the early 1960s, beef producers have been concerned about price-depressing effects of beef and veal imports on live cattle prices (U.S. Senate 1964a,b, 1976a,b, 1978). The concern about imports reached a peak in 1964 with the passage of the Meat Import Act. This concern continues as evidenced by the House of Representatives bills 1995, 1996, 1997, and 1998 currently under consideration by the 96th Congress. Each of these bills proposes further restrictions on meat imports. However, both imports and exports of cattle, beef, veal, and beef by-products have an impact on live cattle prices. Imports are only one side of the larger issue of international trade in these products. For example, the dollar value of exports has been considerably greater than the dollar value of imports of beef, veal, and beef by-products for three of the four years, 1975–1977 (table 1).

Much attention has been given to the adverse impact of imports on domestic live cattle prices through models which directly examined this relationship or by imputing the impacts from econometric models of the beef sector (Edwards, Ehrich and Usman, Folwell and Shapouri, Freebairn and Rausser, Houck 1974, 1977, Jackson, Langemeier and Thompson, and Schmitz and Nelson). However, these researchers have neglected the impact of beef and beef by-product exports on domestic live cattle prices. In this note, these impacts are quantified. Beef exports are not examined because they comprised about 0.35% of total U.S. beef production in 1977 (Blake and Coppersmith).

The Model

The prices packers are willing to pay for live cattle are a function of the prices they receive for the by-products and the price they receive for carcasses. Thus, live cattle price (LCP) may be divided into two components, one component attributable to by-products (BP) and the other to beef (B),

$$LCP = BP + B. \tag{1}$$

Martin Blake is an assistant professor and Tom Clevenger is a professor in the Department of Agricultural Economics at New Mexico State University, Las Cruces.

Journal Article No. 721 of the New Mexico State University Agricultural Experiment Station.

The portion of live cattle price attributable to beef is a function of the supply and demand factors for beef including net imports of beef. The portion of live cattle prices attributable to beef by-products may be thought of as a function of the supply and demand factors for these by-products, including net exports of beef by-products. However, live cattle are purchased and slaughtered primarily for their value as beef, not for their by-product value. Thus, the supply of beef by-products may be viewed as derived from the number of cattle slaughtered, not as a function of the price of by-products. Because of this, the price of beef by-products can be viewed as a function of demand factors alone. This relationship may be expressed as

$$BP = f(E, DDBP), \tag{2}$$

where BP is the portion of live cattle price attributable to by-products; E, the exports of beef by-products; and $DDBP$, the domestic demand for beef by-products.

The equilibrium price of by-products is determined through use of the market clearing condition. Quantity supplied is composed of imports (I) and domestic production (DP), while quantity demanded is composed of domestic demand (DD) and exports (E). This may be expressed as

$$DP + I = DD + E, \text{ or,} \tag{3}$$

$$DP = DD + (E - I), \text{ and} \tag{4}$$

$$1 = \frac{DD}{DP} + \frac{E - I}{DP}. \tag{5}$$

Because $DP = DD + (E - I)$, estimating BP as a function of $\frac{DD}{DP}$, $\frac{E-I}{DP}$, and an intercept term would lead to a problem of perfect multicollinearity. Thus, a formulation that includes both $\frac{E-I}{DP}$ and an intercept term indirectly accounts for domestic demand. The equilibrium price of beef by-products may be expressed as

$$BP = f\left(\frac{E - I}{DP}\right). \tag{6}$$

The measure employed, the portion of live cattle price attributable to by-products, is from the U.S. Department of Agriculture (USDA) *Livestock and Meat Statistics*, which reports the portion of gross

Table 1. Value of U.S. Imports and Exports of Cattle, Beef, Veal, and Beef and Veal By-Products, 1975–78

Item	1975 Imports	1975 Exports	1976 Imports	1976 Exports	1977 Imports	1977 Exports	1978[a] Imports	1978[a] Exports

[a] Preliminary.

[b] Although the export figures are for beef and veal offal, the import data include all animal offal.

farm value attributable to edible and inedible by-products. Gross farm value is the market value to producers for a quantity of live animal equivalent to one pound of retail cuts.

The farm by-product allowance has accounted for about 10.3% of the gross farm value since 1970 (Blake and Coppersmith). The gross farm value and farm by-product allowance for beef may be transformed to an equivalent liveweight price per pound by dividing by the farm product equivalent. The farm product equivalent is an estimate of the amount of live animal needed to produce one pound of retail cuts. The USDA reported a farm product equivalent for beef of 2.36 prior to 1970 and gradually increased it to 2.40 in 1976. The endogenous variable used in this study is the transformed farm by-product allowance (*FBPA*). This variable measures the portion of the average liveweight farm price of cattle in cents per pound attributable to beef by-products. Because live cattle prices have been divided into two components (1), use of *FBPA* as the endogenous variable permits an examination of the impacts that beef by-product exports have on live cattle prices. The theoretical relationship estimated in this article is

$$FBPA = f\left(\frac{E - I}{DP}\right). \tag{7}$$

Major by-products of beef production are edible tallow, inedible tallow and grease, hides and skins, and beef offal. Data are available on imports and exports of edible and inedible tallow in the U.S. Department of Commerce's *Current Industrial Reports* and for imports and exports of skins and hides in USDA's *Agricultural Statistics*. Data on imports and exports of beef offal are available in *Foreign Agricultural Circular—Livestock and Meat* (USDA).[1] Data are also available on the domestic production of edible and inedible tallow in *Current Industrial Reports*. Although no data are available for domestic production of skins and hides or beef offal, reasonable estimates for these quantities can be derived. An estimate of the domestic production of skins and hides is obtained from the number of cattle and calves commercially slaughtered (USDA *Livestock and Meat Statistics*). An estimate of the domestic production of beef offal is obtained by multiplying the number of cattle commercially slaughtered by 36.1 pounds of offal production from a 1,000 pound animal, a figure currently used by USDA.

The exogenous variables used in this analysis are derived from these data on imports, exports, and domestic production of beef by-products. Net exports as a percentage of domestic production for each of the major by-product items are the four exogenous variables used in this analysis.

A major percentage of beef by-products is exported. U.S. exports of inedible beef tallow and grease have averaged 45.1% of production 1970–77. Exports of skins and hides have averaged 51.1% of production for the same period. Beef offal and edible tallow exports have been relatively less important, averaging 12.5% and 4.7% of production, respectively, 1970–77 (Blake and Coppersmith).

Because imports of these by-products are very small, net exports are used rather than accounting directly for by-product imports. Using net exports divided by the domestic production for each of these by-products establishes the relative importance of the export market for each by-product and permits an evaluation of its impact on the portion of live cattle price attributable to by-products.

[1] Data are available on beef offal exports in the *Foreign Agricultural Circular—Livestock and Meat* from 1966 to date. One method of obtaining a longer time series for beef offal exports is to use exports of total fresh or frozen variety meats, reported in *Agricultural Statistics*. Exports of total fresh or frozen variety meats include not only beef offal, but offal from other animals. A correlation coefficient of 0.98 was estimated for exports of beef offal and exports of total variety meats for 1966–77.

The estimated model for the time period 1958–77 is

$$FBPA = \underset{(1.69)}{3.66} - \underset{(-1.66)}{0.09}\ PCTIT + \underset{(1.77)}{0.10}\ PCTET + \underset{(1.15)}{0.03}\ PCTSH + \underset{(1.48)}{0.11}\ PCTO,$$
$$R^2 = 0.763 \qquad F = 12.09$$

where t-values are shown in the parentheses; *FBPA* is the portion of the annual average liveweight farm price of cattle attributable to beef by-products (cents per pound); *PCTIT*, annual net exports of inedible beef tallow and grease as a percentage of domestic production; *PCTET*, annual net exports of edible beef tallow as a percentage of domestic production; *PCTSH*, annual net exports of cattle hides and calf skins as a percentage of domestic production; and *PCTO*, annual net exports of beef offal as a percentage of domestic production.

Analysis

The R^2 of 0.763 implies that the export market accounts for a major share of the variation in the portion of annual average liveweight farm cattle price that is attributable to by-products. The F-value of this model was 12.09, which is significant at the 99.9% level.

Because beef tallow is a major dollar value component of beef by-product exports (table 1), the negative coefficient for *PCTIT* was not expected. This negative sign would imply that for each 1% increase in the amount of inedible tallow production that was exported, the average annual domestic live cattle price declined by 0.09¢ per pound. This negative impact on domestic live cattle prices may be attributed to the large percentage of total world exports of inedible tallow accounted for by U.S. exports. For the period 1973–75, U.S. exports of inedible tallow comprised about 66% of total world tallow exports (*Agricultural Statistics*). Because total world tallow exports include both edible and inedible tallow, the 66% figure is a conservative estimate of the importance of U.S. inedible tallow exports in the world market. The quantity of inedible beef tallow exports averaged about 200 times the exports of edible beef tallow. With the United States having about two-thirds of the world inedible tallow export market, it is possible for additional U.S. exports to have a price-depressing effect on this market. This appears to have been the case for 1958–77, as indicated by the negative sign for the regression coefficient *PCTIT*. The coefficient for *PCTIT* was significant at the 88% level.

The mean value of *PCTIT* was 45.13, which resulted in a −4.06¢ per pound impact on live cattle prices. *PCTIT* ranged from 38.89 in 1958 which resulted in a −3.50¢ per pound impact on live cattle prices, to 52.33 in 1971, which resulted in a −4.71¢ per pound impact on live cattle prices.

Coefficient for *PCTET* was significant at the 90% level. The coefficient of *PCTET* may be interpreted as a 1% change in the amount of edible tallow production that was exported resulting in a 0.10¢ per pound change in live cattle prices. The mean value of *PCTET* was 3.17, which had a 0.32¢ per pound impact on live cattle prices. *PCTET* ranged from 0.58 in 1966, which resulted in a 0.06¢ per pound impact on live cattle prices, to 11.38 in 1974, which resulted in a 1.14¢ per pound impact on live cattle prices.

The coefficient for *PCTSH* indicates a 1% change in the amount of calf skin and cattle hide production that was exported resulted in a 0.03¢ per pound change in live cattle prices. Although the coefficient appears small relative to the others, the mean value of *PCTSH* was 37.18, which resulted in a 1.12¢ per pound impact on live cattle prices. *PCTSH* ranged from 11.11 in 1959, which resulted in a 0.33¢ per pound impact on live cattle prices, to 66.24 in 1972, which resulted in a 1.99¢ per pound impact on live cattle prices. The coefficient for *PCTSH* was significant at the 73% level.

The coefficient for *PCTO* was significant at the 84% level. This coefficient indicates that a 1% change in the amount of beef offal production that was exported resulted in a 0.11¢ per pound change in live cattle prices. The mean value for *PCTO* was 17.78, which resulted in a 1.96¢ per pound impact on live cattle prices. *PCTO* ranged from 7.93 in 1958, which resulted in a 0.87¢ per pound impact on live cattle prices, to 24.87 in 1977, which resulted in a 2.74¢ per pound impact on live cattle prices.

Implications

The impacts that beef by-product exports have had on live cattle prices can best be seen by looking at the high and low values for each of the by-product variables during the time period considered. The impacts that exports of inedible tallow, edible tallow, skins and hides, and offal have had on the price of live cattle per hundred weight ranged from −$3.50 to −$4.71, $0.06 to $1.14, $0.33 to $1.99, and $0.87 to $2.74, respectively. These may be compared with the impact of beef imports on live cattle prices estimated by Freebairn and Rausser. They examined the effect of a 200 million pound increase in beef imports on live cattle prices and reported that the price per hundredweight of slaughter steers would decline by $0.56, cull cows would decline by $0.94, and feeder calves would decline by $0.69. During 1970–76, the lowest level of fresh or frozen beef and veal imports was 1,079 million pounds in 1974, and the highest level was 1,349 million pounds in 1973 (USDA *Agricultural Statistics*). Thus, the largest change in imports during this period was 270 million pounds. Hence, the 200 million pound increase in beef imports examined by Freebairn and Rausser is nearly as large as the difference between the largest and smallest levels of beef and veal imports 1970–76. As may be

seen, the impacts of beef by-product exports are large relative to the impact of beef imports.

Currently, there is considerable interest in beef imports. One implication of this study is that some, or even most, of this attention might profitably be shifted to the by-product export markets. For example, there seems to be much potential for increasing live cattle prices by examining the markets for inedible tallow. Prior to 1972, the negative price impact of inedible tallow exports exceeded the sum of the positive price impacts of the other three by-product exports. The reverse was true for 1972–77. This reverse has not been due to any great decline in the impact of inedible tallow exports, but has resulted from a rather large increase in the sum of the other three components. The large negative effect of inedible tallow exports on live cattle prices and the fact that the United States accounts for about two-thirds of world exports for this commodity imply that live cattle prices may be increased by allocating less inedible tallow to the export market. A full assessment of this potential requires detailed information on the price elasticity of demand in the various markets for inedible tallow. Furthermore, such knowledge of elasticities would be useful for all beef by-products.

Factors Affecting Corn Basis in Southwestern Ontario

Larry Martin, John L. Groenewegen, and Edward Pidgeon

Pricing performance of futures markets for seasonally produced, storable commodities often has been evaluated in part by determining whether or not the basis at the delivery point reflects the theoretical factors expected to affect it.[1] These factors include marginal net storage costs (Working, Brennan, and Weymar), market liquidity (Gray 1960 and 1967, Martin and Storey) and market characteristics unique to a specific commodity (Ward and Dasse).

Futures markets for these commodities also are used to establish current prices at nondelivery points. Following the argument of Ward and Dasse, if pricing performance at nondelivery points is satisfactory, local basis should reflect market characteristics unique to the local area because it is a measure of the value of a commodity relative to the delivery point.

Futures markets also are used to forward price grains at nondelivery points either by hedging or forward contracting. In either case, expectations of basis are important in establishing forward prices. Most extension literature stresses the importance of understanding the local basis and asserts that local basis is affected by local market conditions (e.g., Kenyon and Blakely). Yet for the few cases in which analyses of local basis have been undertaken, relatively naive models have been used to explain basis variations, such as moving averages or basis at the time a hedge is initiated (Kenyon and Blakely, Driscoll and Blakley, and Heifner 1966). The ability to explain nondelivery point basis using variables reflecting local market conditions is important for evaluating pricing performance and for providing local traders and hedgers an understanding of the factors which cause variations in the local basis.

In this paper an analysis of nondelivery point basis is undertaken with the objective of providing information for these two purposes. The analysis is carried out by constructing a hypothetical model to explain variations in local basis and then testing it by applying it to basis data for southwestern Ontario.

Larry Martin is associate professor of agricultural economics, University of Guelph, and L. J. Norton Visiting Professor of Agricultural Marketing, University of Illinois; John L. Groenewegen and Edward Pidgeon are graduate students at the University of Minnesota and the University of Guelph, respectively.

The research for this study was supported by Agriculture Canada and the Ontario Ministry of Agriculture and Food.

[1] Basis is simply the difference between the spot and a futures price on a given day. Our concern here is with the basis when corn is marketed. This will be termed "ending basis."

The Ontario Market for Corn and Its Pricing Mechanism

Ontario produces most of Canada's corn, and production has trended upward from 33 million bushels in 1962 to 154 million bushels in 1977. Because of available heat units, the majority of the province's production occurs in the southwestern counties. The major pricing point for southwestern Ontario is Chatham, an inland terminal with rail links to Lake Huron, eastern Ontario, and Montreal, where Ontario corn normally competes with imported U.S. corn.

As a result of the increasing trend in Ontario's corn production, the province gradually has moved from a deficit to a surplus position. At the same time, variations around the trend and cyclic growth in the province's livestock production have resulted in substantial year-to-year variation in the local supply-demand balance, contributing to large variations in the local basis. For example, during crop years 1962–71, Martin noted that the Chatham basis in late October varied from \$.20 under the December futures price to \$.07 over, while the mid-June basis varied from \$.15 under to \$.13 over the July contract. Since 1971, variations in the Chatham basis have become even larger, as is illustrated by the weekly basis observations in figure 1 for crop years 1972, 1974, and 1975.[2]

Three factors in the above discussion—the landlocked location of the Chatham market, variations in the local supply-demand balance, and competition with U.S. corn—are important in establishing prices and basis in southwestern Ontario. These three factors combine to result in three alternative pricing and basis situations for southwestern Ontario. First, when Ontario's production is less than the province's demand, Ontario and U.S. corn compete in central or eastern Ontario. The price in southwestern Ontario tends to be the price of U.S. corn at Chicago plus lake freight to Canada (Montreal or Prescott) plus tariff, elevation, and rail transfer cost to, e.g., central Ontario less rail transfer from Chatham to central Ontario.

The second occurs when Ontario's production

[2] These are obtained from Thursday market closes each week, adjusted to Canadian dollars using weekly exchange rates, and represent the nearby basis—i.e., from October through November, basis is calculated from the December contract; from December through February, it is calculated from the March contract, etc. Three crop years were selected to show the range of variation.

exceeds her demand and Ontario and U.S. corn compete in Quebec and the Maritimes. In this case, no rail transfer costs are incurred for U.S. corn and the southwestern Ontario price tends to be the landed price of U.S. corn at Montreal less rail costs from Chatham to Montreal.

The third case occurs when eastern Canada has surplus production and Canadian and U.S. corn compete on the export market. (Because the United States imposes a \$.25 tariff on imported corn, Canadian exports to the United States are, for all practical purposes, precluded.) Under these circumstances, U.S. corn does not enter Canada but is transferred to oceangoing vessels and no tariff is charged. Hence the southwestern Ontario price tends to be the price of U.S. corn at Montreal (in bond, not including tariff) less rail costs from Chatham to Montreal.

The foregoing indicates that the southwestern Ontario price (and basis) falls relative to the price of U.S. corn as the point of competition moves eastward. Implicit in this statement is the hypothesis that the local (eastern Canada) supply-demand balance is an important variable in explaining basis variations.

The present discussion omits a number of other factors which may affect the basis and which are addressed in the following section. However, it is sufficient to form a notion about the general relationship between U.S. and Ontario corn prices and to form a basis residual used in the analysis.

Because of the time and distance required to ship corn from Chicago to Montreal, the U.S. export-offering price normally is the nearby futures price plus a loading charge. This has been documented by Regli and confirmed by the authors in conversations with the trade in Canada. Based on this tendency, the foregoing discussion, and an initial assumption that the only influences on the Chatham price are the Chicago price and all costs incurred to move Ontario and Chicago corn to Montreal, the Chatham price normally would be the demand area price at Montreal less transfer and handling charges between Chatham and Montreal. The demand area price at Montreal is the nearby futures price and the loading charge at Chicago (adjusted for the current exchange rate) plus transfer, tariff, and handling charges to Montreal. Hence, given the assumptions made, the Chatham basis would be equal to the loading charge at Chicago plus transfer, tariff, and handling charges from Chicago to Montreal, less transfer and handling charges from Chatham to Montreal.

Of course, as indicated previously, Montreal is not always the Canadian pricing point for U.S. corn; moreover, other variables affect the Chatham basis. Thus, the assumptions made above must be relaxed, and the Chatham basis at a given point in time consists of two components: net spatial costs (loading, tariff, transfer, and handling charges) and a basis residual. Rail costs from Chatham to Montreal, the tariff, and average annual vessel rates are known and can be acquired as time-series data. However, vessel rates, handling, and loading charges vary within a year with changes in the demand for and supply of these services and time-series data on them are not available. The known component can be eliminated from the model while the unknown component is included in the basis residual.

The remaining basis residual is the focus of our empirical analysis. The model developed to explain the residual is presented below.

The Model and Results

The model to explain basis residual is specified as

$$BR_t^i = f(S^i, IPOC_t, CCP_t, USCP_t, WFGA_t, D_i),$$

where BR_t^i is the basis residual in month i of crop year t, as defined above; S^i is seasonality; $IPOC_t$ is a ratio of eastern Canadian production to eastern Canadian consumption; CCP_t is Canadian corn production in year t; $USCP_t$ is U.S. corn production in year t; $WFGA_t$ is availability of western feed grains to the domestic market in eastern Canada; and D_i is a series of (0–1) dummy variables which represent short-run pricing aberrations.

The reasons for including each variable and its expected effect on the basis will be developed below along with the results of the analysis. Equations for average monthly basis residual were estimated with data from crop years 1962 through 1976, using ordinary least squares procedures. All variables were included initially in the estimating equations. Where preliminary estimations resulted in t-values of less than 1.0 on individual variables, those variables were deleted and the equations reestimated. The final equations are presented in table 1 for October through July. The results for August and September showed that the only market variable having a significant effect on basis in these months is, not surprisingly, the size of the succeeding crop year's crop. Since the succeeding crop's size is not known in August or September, it must be concluded that basis in these months is exceeding difficult to predict.

Seasonality

A number of factors combine to cause seasonality in the basis at Chatham. As with most seasonally produced commodities, harvest period prices in Ontario are bid down relative to the futures price until the harvest glut is cleared from the producing area. During the late fall and winter, the Ontario basis exhibits the characteristic increase which is expected after a harvest glut has been reduced. For Ontario, this seasonal pattern is exacerbated because Great Lake-St. Lawrence shipping is closed and Ontario corn competes only with U.S. or Western Canadian feed grains moved into Eastern terminals in the fall or with grain shipped by rail from

Table 1. Monthly Equations for Ontario Basis Residual (*t*-values in parentheses)

Month	Intercept	*IPOC*	*CCP*	*USCP*	*WFGA*	*D72*	*D73*	*D74*	R^2	*SEE*
October	.384	−.609 (−5.26)							.68	.045
November	−.532		−.313 (−6.97)	.126 (4.67)			.139 (3.02)		.85	.042
December	−.361		−.232 (−4.36)	.088 (2.77)			.201 (3.68)		.76	.050
January	.334	−.458 (−3.59)				.075 (1.49)	.097 (1.89)		.66	.049
February	.372	−.493 (−3.83)				.116 (2.27)	.079 (1.51)		.69	.049
March	.313	−.440 (−3.51)				.238 (4.71)			.75	.049
April	.284	−.402 (−3.41)				.206 (4.40)	.188 (3.94)		.82	.045
May	.321	−.278 (−1.64)			−.157 (−2.26)	.146 (2.14)	.294 (4.41)		.73	.062
June	.335	−.217 (−1.09)			−.187 (−2.31)	.346 (4.31)	.193 (2.48)		.71	.073
July	.514	−.441 (−2.64)			−.142 (−2.22)	.292 (4.68)		.166 (2.49)	.76	.061

Note: Units in which the explanatory variables are measured are: *IPOC*, ratio of Eastern Canadian production to Eastern Canadian consumption with 1 occurring when the two are equal; *CCP*, 1 = 100 million bu.; *USCP*, 1 = 1 billion bu.; *WFGA*, 1 = 1 million tonnes.

these areas. The latter is relatively costly and tends to result in Ontario prices being bid up relative to the futures price.

Great Lake-St. Lawrence shipping is opened during March or April, resulting again in increased competition for the eastern Canadian market and a narrower basis. During the late spring and summer, Ontario prices have tended to increase relative to the futures price because Ontario's crop has not been sufficiently large to meet eastern Canada's demand during these months.

The resulting seasonal basis pattern is apparent in figure 2, which contains the average nearby Chatham basis for each month of crop years 1971–75. To account for this seasonality, and on the hypothesis that different factors affect the basis in different months, a separate equation was estimated for each month of the crop year. The results in table 1 tend to support this hypothesis. (As in figure 1, basis in figure 2 is calculated from the nearby future and is adjusted for exchange rates.)

Ratio of Eastern Canadian Corn Production to Consumption

This variable was included to account for competition in the eastern Canadian market between domestic and U.S. corn, as discussed in the previous section. As the ratio approaches or exceeds unity, domestic and imported corn would compete east of Montreal or on the export market and the Chatham basis would be bid down for the reasons explained earlier. Thus, the variable should be related inversely to the basis throughout the crop year.

The results are as expected. The ratio is significant in all months except November and December when harvest variables explain much of the basis variation (see below).

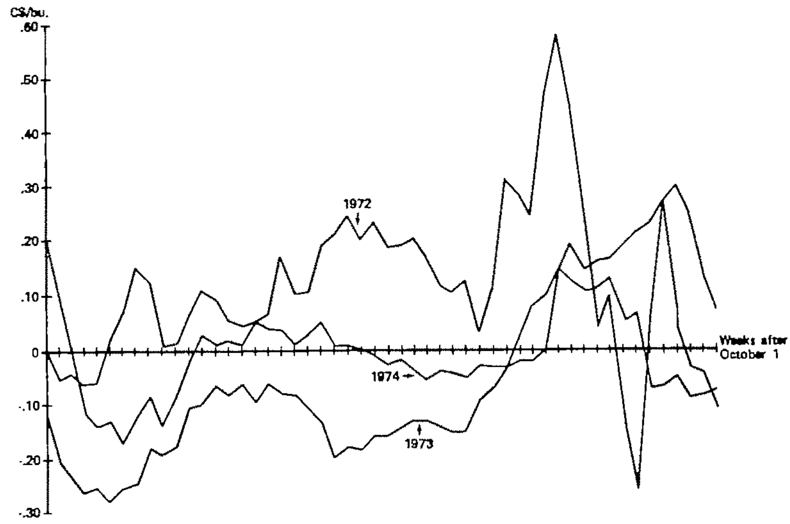
Canadian Corn Production

This variable was included because of the expected relationship between the size of the crop and storage charges in Ontario. The larger the crop, the greater the demand for storage; hence, the local basis would be expected to fall to cover increased storage costs.

The results are consistent with the expectation. The Canadian crop is a significant variable during the harvest period as would be anticipated because this is the period when demand for storage is greatest.

U.S. Corn Production

U.S. corn production is included for two reasons. First, the size of the crop could be a determinant of short hedging pressure at harvest time. A large U.S. crop would place downward pressure on futures prices. Second, a large U.S. crop would motivate shipping more corn through the Great Lakes-St. Lawrence system in the fall before the close of navigation. This, in turn, would increase the demand for transport and handling services during this period, thereby increasing the costs of these



Note: See footnote [2] for explanation of figure.

Note: See footnote [3] for explanation of figure.

Figure 2. Monthly corn basis, averaged over crop years 1971–75, Chatham, Ontario

services. Hence, the size of the U.S. crop is a proxy for the demand for these services. Both factors suggest that the size of the U.S. corn crop would be related directly to the Ontario basis during the fall.

Again, the analysis confirms the expectation as indicated by the coefficients for November and December in table 1.

Western Feed Grain Availability

Western feed grain availability is included as a proxy for Canadian Wheat Board and federal feed grain pricing policy. These policies have changed often and markedly during recent years and are therefore both unquantifiable and unpredictable. However, a measure of availability is included on the ground that competition from western feed grains should be expected to affect the eastern corn basis. Availability was measured initially as stocks of western feed grains in lakehead and eastern elevators. However, in initial runs, this variable was found to carry no statistical significance. This is likely because the data do not separate stocks intended for domestic and export markets.

As an alternative, actual movements of western feed grains to the domestic eastern market were used in the analysis. This variable is expected to be related inversely to the basis. The expectation is confirmed by the coefficients on the variable from May onward in table 1.

Dummy Variables

Dummy variable D72 was included for January through July of crop year 1972 (i.e., calendar year 1973) to account for an inversion in corn futures prices during this period. As a result, U.S. export prices apparently were based on the spot instead of the nearby futures price, and the Ontario basis showed substantial premia over the futures prices.

Dummy variable D73 was included for the months of November through June (except March) of crop year 1973. During that crop year, the Canadian Wheat Board established initial prices for Board grains at high levels. This led to the delivery of most board grains to the Canadian Wheat Board, which then exported them. As a result, there was little movement of western grains to the East and therefore a premium was bid on Canadian corn. In March 1974, when navigation opened, the premium disappeared, reflecting expected U.S. corn imports. However, little U.S. corn was imported until July; so the premium on Canadian corn reappeared from April through June.

Dummy variable D74 was included for July and August of crop year 1974. The 1974 corn crop in Canada was of record size. In the fall, trade sources believed Canada would be in a surplus position and, accordingly, exported a record 10 million bushels early in the crop year. Subsequently, it became apparent that domestic demand for corn had been underestimated and substantial amounts of U.S. corn were imported late in the crop year.

The results in table 1 indicate that the market aberrations each had considerable positive impact on the local basis, as expected.

Sensitivity of Basis Residual to the Explanatory Variables

It is of interest to show the sensitivity of basis to changes in the explanatory variables. While this normally would be done using elasticities, elasticities are of little meaning in this analysis because of the small magnitude of the dependent variables. Instead, the absolute change in basis associated with a 10% change from the mean in each explanatory variable is presented in table 2.

Data in table 2 indicate that basis residual is quite sensitive to most of the variables. Of the eight months for which the ratio variable (*IPOC*) is significant, a 10% change results in 3¢ per bushel or more change in basis in six months. Domestic corn consumption averaged about 110 million bushels per year over this period. Hence, the 10% change in *IPOC* represents approximately 8.5 million bushels in Canadian production.

The basis residual in November and December is quite sensitive to Canadian and U.S. corn production. The greater sensitivity implicit in the U.S. production variable is initially surprising; however, a 10% change in U.S. production is more than five times total Canadian production.

Basis residual for May through July is not particularly sensitive to western feed grain availability. However, during the sixteen years of the analysis, shipments of western feed grains to eastern Canada varied from virtually nil to 1.03 million tons. A change in shipments of 10% from the mean is only 72,000 tons; but year-to-year changes obviously can be far in excess of this.

Conclusions

The analysis suggests that a substantial amount of the variation in the southwestern Ontario basis is explained by variables reflecting local market conditions. During the fall months, the size of the Canadian and U.S. crops is the most important factor. During the winter, when the eastern Canadian market is essentially closed except to relatively costly rail access from the United States and

March	−.005	−.033			
April	.005	−.031			
May	.026	−.021			−.011
June	.071	−.016			−.013
July	.107	−.034			−.010

[a] Means of the explanatory variables are: *IPOC* = .76 = ratio of Canadian production to consumption; *CCP* = .86 = 86 mil. bu.; *USCP* = 5.7 bil. bu.; *WFGA* = .72 = 720 thousand tonnes.

western Canada, the only significant factor is the size of the Canadian crop relative to local demand. After navigation is reopened in the spring, both local production relative to demand and the availability of western feed grains have significant effects. The relative insensitivity of the variable representing western feed grains suggests that Canadian policy affecting western grains is not normally as significant a factor in determining Ontario corn prices as is often perceived in Canada. This inference must, however, be qualified by the difficulties in measurement of the variable and by the coefficients on *D*73 which suggest that events in western Canada are important in extreme circumstances.

That the basis for corn in southwestern Ontario adjusts to local market conditions as theory implies provides some reassurance about the market's pricing performance. However, the analysis does not purport to provide evidence on whether prices are optimum in any sense. From a practical standpoint, the analysis provides information that could be useful to local traders and hedgers in understanding the factors which affect the basis.

Revisiting the Advertising-Concentration Issue

Ronald W. Ward and Robert M. Behr

Increases in advertising efforts are reasonably well documented among most U.S. industries (Nelson, p. 43). Yet, the economic controversy relating to the causal linkage between advertising intensity and changing market structures is not settled. Advertising can represent a major barrier to entry by its role in achieving product differentiation. In contrast, advertising may enhance competition with the dissemination of information through competitive advertising. While the advertising issues are varied and complex, this paper will set forth additional empirical evidence showing the relationship between advertising intensity and changing industry structure. In particular, the intensity of advertising across industry levels of concentration will be addressed and reference will be given to the food industries.

Studies suggesting that advertising leads to increased concentration have at the best been mixed (Blair). The argument suggesting that the advertising intensity varies positively (or negatively) with concentration has been slightly more definitive. Schmalensee argued that as concentration increases and profits rise, the marginal unit of sales becomes more profitable and it pays more to advertise to capture these additional sales (Mann, p. 150). Strickland and Weiss developed a simultaneous equation model with one equation relating advertising intensity to concentration where both variables are endogenous. Their analyses show that little bias is evident when the advertising intensity equation is estimated as a single equation in contrast to the simultaneous equation results (p. 1116). Because the primary focus of this analysis is to gain a better understanding of changing advertising intensity, the relationship is estimated in a single equation framework relying on Strickland and Weiss's conclusions as to the degree of bias that may occur.

The basic arguments for concentration influencing advertising intensity are two. (*a*) With increased concentration, firms recognize their rival's advertising reaction curve and will thus decrease their advertising effort on the assumption that it only has a neutralizing effect on the rival's advertising. Or, (*b*) with increased concentration, firms will substitute nonprice competition via advertising for price competition. The second argument implies a positive association between advertising and concentration, while the first argument suggests a negative relationship. These effects in turn lead to the public policy dialogue concerning the net social benefits derived from price versus nonprice competition.

Advertising-Concentration Linkage

Dorfman-Steiner's studies of price and nonprice decisions provide a clear linkage establishing the static optimal advertising decision rule to be related to both price and nonprice decisions (Needham, p. 87; Ward, p. 500). If ϵ_a and ϵ_d are the firm's elasticities of advertising and demand, then $A/S = \epsilon_a/|\epsilon_d|$ according to the static rule where A is advertising expenditures and S is sales.

The current issue is how the advertising intensity (A/S) changes with industry concentration (C) and how concentration influences both ϵ_a and $|\epsilon_d|$. The advertising and concentration relationship obviously is confounded in the effect concentration has on both elasticities. If concentration leads to greater economies of scale to advertising and increased product differentiation (i.e., $\partial\epsilon_a/\partial C > 0$) and a corresponding reduction in substitutes (i.e., $\partial|\epsilon_d|/\partial C < 0$), then it always follows that advertising intensity will increase with concentration. The adjustments in ϵ_a and ϵ_d are not altogether clear, however.

The firm's advertising elasticity further has been shown to be related to the rival's advertising response (Needham, p. 85). Assuming that the industry structure is such that rival response is not apparent, then the arguments for a neutralizing and/or retaliatory advertising response are not relevant. However, as concentration increases anticipated rival response can not go unnoticed.

The concentration-intensity linkage is further confounded when one turns to the effects of concentration on the elasticity of demand. Price elasticity of demand is related to the rival's response, and this response is influenced by the level of concentration. With no rival response it is relatively easy to show that the firm's demand becomes less elastic with increased concentration. If increased rival response to firm price changes is anticipated, advertising will be substituted for price competition. However, as concentration increases, rival impact may be lessened and the need to substitute nonprice for price competition would be reduced.

Table 1. Hypothesized Effects of Concentration on Advertising Intensity [$\partial(A/S)/\partial C$]

	$\partial\epsilon_a/\partial C$		
$\partial\lvert\epsilon_d\rvert/\partial C$	+	0	−
+	?	−	−
0	+	0	−
−	+	+	?

Note: The signs within the table follow from the relationship where $\partial(A/S)/\partial C = (1/\lvert\epsilon_d\rvert)[\partial\epsilon_a/\partial C - (A/S)(\partial\lvert\epsilon_d\rvert/\partial C)]$, as derived using the Dorfman-Steiner theorem.

The problem with hypothesizing the advertising-concentration relationship is illustrated in table 1, where the alternative signs for $\partial(A/S)/\partial C$ are shown. Given the difficulties in determining the signs from the effects of concentration on ϵ_a and ϵ_d, an alternative would be to estimate directly the relationship between advertising and concentration. The empirical results may then suggest the relative importance of ϵ_a and ϵ_d to the advertising-concentration issue.

Advertising-Concentration Model

The analysis from the above section indicates that the advertising-concentration relationship ultimately will depend on empirical models. To date, mixed results have been reported when estimating the model where $A/S = f(C)$ (Mann, pp. 142–56). While the theoretical problems cannot be compromised, many of the difficulties with previous studies can be related to model misspecification, incompleteness in data classification, and inappropriateness of the estimation techniques. Recent studies by Ornstein have addressed the empirical problems of relating advertising and concentration. His studies show a positive but statistically weak relationship between concentration and advertising. Additional studies by Brush provide support for the validity of the data series developed by Ornstein.

For the present problem, concentration and advertising data are taken from the SIC for four-digit industries. The value of shipments of the top four firms relative to total shipments is used as a measure of concentration and the advertising data from Ornstein's study are used (p. 45). Shepherd provided an adjusted data series for the 1966 four-firm concentration ratios for the purpose of correcting what was believed to be a problem with the data similar to that used by Ornstein. Brush's studies of Ornstein's models using the corrected data led him to conclude that "correction of errors in the official Census concentration ratios has had little effect on the statistical estimation of the advertising concentration relationship . . ." (p. 985). For this reason, the initial data reported by Ornstein will be used. The advertising and concentration levels are measured across industries and the SIC codes are classified according to consumer versus producer goods, and durable versus nondurable goods. Many of the consumer nondurables are food industries. The cross-sectional data of four-digit industries are recorded over the years of 1947, 1963, and 1967.

Both Ornstein's and Strickland and Weiss' models are specified such that the intensity may decline with high levels of concentration. Ornstein's results supporting a declining intensity are statistically weak. Whereas, while Strickland and Weiss' statistical results are strong, there appears to be some difficulty with changes in the signs of their advertising relationship as they change the specification of their model (p. 1116). In the current model, the specification facilitates a nonlinear relationship initially assuming that the effect of concentration at least approaches some upper limit. The alternative where the intensity may decline is considered. The asymptotic function follows as the adjustments in ϵ_a and $\lvert\epsilon_d\rvert$ can be expected to approach limits such that $\lim \partial\epsilon_a/\partial C = 0$ and $\lim \partial\lvert\epsilon_d\rvert/\partial C = 0$.

The response to concentration may differ across industries simply because of the differences in both advertising and price elasticities for particular product categories. Finally, there may be reason to suspect that advertising intensity has increased since 1947 as a partial result from increased availability of advertising media. Each of the adjustments above have been ignored in most model specifications or at least have been treated in separate models.

Using the above arguments, the model specification below can be used to test the advertising-concentration relationship.

$$\text{(1)} \qquad \frac{A}{S} = \exp^{\{\tau_0 + \tau_1/C + \mu\}},$$

where

$\tau_0 = \beta_0 + \beta_1 PRO + \beta_2 DUR + \beta_3 T_1 + \beta_4 T_2$, and
$\tau_1 = \alpha_0 + \alpha_1 PRO + \alpha_2 DUR + \alpha_3 T_1 + \alpha_4 T_2$, and
A/S is the advertising-sales ratio (i.e., $0 \le A/S \le 100$);[1] C is the four-digit, SIC industry classification ($0 \le C \le 100$); PRO is the type of good (-1, producer; $+1$, consumer); DUR is a perishability measure (-1, durable; $+1$, nondurable); T is year where ($T_1 = 1$, $T_2 = 0$, for 1947; $T_1 = 0$, $T_2 = 1$, for 1963; $T_1 = 0$, $T_2 = 0$, for 1967). Note that τ_0 and τ_1 include the effects of PRO, DUR, and T, and both the level of advertising intensity and the response of advertising intensity to levels of concentration. Finally, the relationship has the asymptotic property where $\lim_{C \to 100} A/S = \exp^{\{\tau_0 + .01\tau_1\}}$, and the limit will change directly depending on the time and product classifications.

Equation (1) is estimated over a sample of 914 observations drawn from the Census of Manufac-

[1] Advertising was not deflated over the three time periods because both sales and advertising are influenced by inflation and the effects of inflation should be netted out in the intensity ratio.

turing (Ornstein, pp. 74–85). Industries differ within the four-digit classification and, hence, the effect of concentration may vary across industries. Therefore, in addition to the classifications by type and perishability, the concentration parameter may have a random component giving $\alpha_0 + \nu$, where ν is an error term having the traditional properties. The dummy variables were defined such that both β_0 and α_0 represent some average effect, and the differences in type are calculated as some adjustment to this average. The randomness in the concentration coefficient is calculated only for this average and not each parameter in (1). The error in (1) is now $\mu + \nu(1/C)$, and the variance is $\sigma_\mu^2(1 + \rho/C^2)$, letting $\rho = \sigma_\nu^2/\sigma_\mu^2$ (Maddala, p. 390).

Equation (1) is estimated by maximizing the concentration likelihood function over values of ρ and the results are shown in table 2. The random coefficient model adds little to the analysis since the maximum value of the likelihood function occurs when $\rho = 0$. Pooling the data across four-digit concentration levels after explicitly accounting for time, type, and perishability does not create estimation problems that might have been expected initially, given the diverse nature of the industries included in the sample.

The statistical results shown in table 2 are probably the strongest to date in support of the relationship between advertising intensity and concentration. The t-values for α_0 and α_1 show the relationship to be significant at the 99% confidence level. Furthermore, response among consumer industries is statistically different from those producer goods industries. This difference is of particular interest since much of agricultural manufacturing relates to consumer goods in the form of food and kindred products. No statistical difference between durable and nondurable goods is evident. Finally the coefficient of determination shows that 39% of the

Note: The model is estimated as a log-reciprocal equation with the dependent variable A/S (see eq. 1). The concentrated likelihood function was maximized when $\rho = 0$.

variation in advertising intensity has been explained. Other factors, some of which are likely unique to each industry, must be addressed in order to further explain intensity. What is important at this stage in the advertising-concentration dialogue is that the relationship has been established. An alternative to model (1), where substantial concentration could eventually lead to less advertising, has been specified as

$$\frac{A}{S} = \exp^{(\tau_0 + \tau_1/C + \mu)} C^{\tau_2}. \tag{2}$$

If $\tau_2 < 0$ and $\tau_1 < 0$, advertising intensity could both increase and decrease with C. This function has the property that $A/S \geq 0$, whereas many of the polynomial functions reported could yield $A/S < 0$. This model was estimated and the empirical results failed to yield any improvements over those in table 2, thus adding more credence to the asymptotic function (Ornstein, Strickland and Weiss).

Product Classifications

As suggested above, a large number of the nondurable industries relate to food and kindred industries. Attempts, however, explicitly to separate out the advertising intensity relationship for this subset of four-digit industries have not proven significant. Rather, the broad product class of consumer versus producer goods is the most important distinction. This would be expected because buyers of producer goods should be less susceptible to product image created by advertising (Mann, p. 139; Strickland and Weiss, p. 1111). Producer products are purchased in sufficient volume and frequency that the alternatives can be appraised. Also, consumer goods are generally more differentiable. Generally, the number of potential buyers are less for the producer versus consumer goods and, hence, the cost of reaching the buyers of producer goods should be less.

When comparing the effects of concentration on consumer versus producer goods, one would expect intuitively the elasticity of demand to change less among those producer versus consumer goods because the product is judged primarily on its characteristics and less on image. Hence, the significance of α_1 in table 2 seems plausible from a theoretical perspective. We are still left with the issue of what happens to ϵ_a for both product categories. If consumers are more susceptible to the image effect in consumer goods as suggested by Mann, then $\partial\epsilon_a/\partial C$ for consumer goods is likely to exceed that of producer goods and the advertising intensity for consumer goods should exceed that of producer goods.

The relationship between producer and consumer goods is illustrated in figure 1 for the nondurable category. Obviously, advertising plays a small role in the very low concentrated industries regardless of the product category. As concentration in-

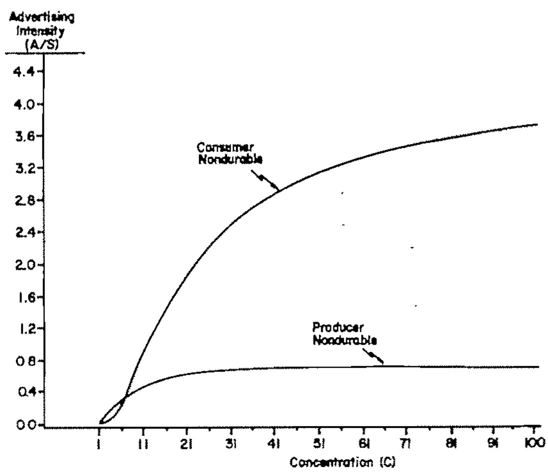

Figure 1. Advertising intensity-concentration relationship for consumer and producer nondurables (1967)

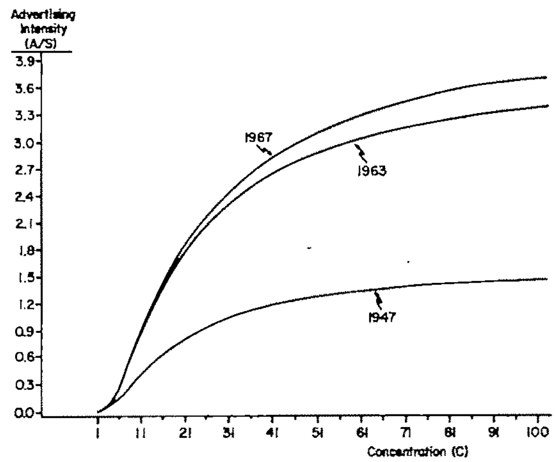

Figure 2. Advertising intensity-concentration relationship for consumer nondurables across time (1947, 1963, 1967)

creases, the advertisng intensity rises rapidly for both goods. Beyond the 20% level very little increase among producer goods industries is evident; whereas, advertising continues to rise rapidly for the consumer goods. The durable category is not shown since the relationship does not differ significantly from that shown in figure 1.

Adjustment over Time

Figure 2 illustrates the adjustments that have taken place since 1947, and the increased use of advertising for each concentration level is most apparent. Advertising intensity has increased and one important consideration is how much increase would have occurred without any change in concentration. Increased intensity with more concentration suggests substitution of nonprice for price competition. Increased intensity over time holding concentration levels fixed does not preclude the substitution for price competition, but it does indicate that greater effort to establish information flows has occurred.

The changing slopes of each response in figure 2 is of special importance in that they clearly show that the effects of structural change on advertising intensity have increased since 1947. The rate of increase in advertising intensity to increases in concentration nearly doubled between 1947–67. While advertising has become more important to concentrated industries, the results still do not totally show how much of this change represented substitution for price competition. A useful extension of the analysis would be to explore an index of price changes among the same industries included in this study.

Figure 3 is useful for depicting the adjustment that has occurred since 1947, holding all concentration levels fixed at their 1947 values. The vertical axis gives the estimated percentage adjustments that would have occurred due to the time alone and is calculated as

$$(3)\quad \frac{(A/S)_{67}}{(A/S)_{47}} - 1 = \exp^{-\left\{\beta_3 + \frac{\alpha_3}{C_{47}}\right\}} - 1,$$

where $C_{47} = C_{67}$ is assumed [see eq. (1)].

Advertising intensity would have declined over time for those industries with concentration under 2%. Whereas for industries having initial concen-

Evaluating the Effects of P.L. 480 Wheat Imports on Brazil's Grain Sector

Lana L. Hall

Econometric analysis of the grain sector of Brazil shows that P.L. 480 wheat imports have had a positive impact on grain production. This was due primarily to government wheat import and domestic price support programs whereby revenues gained from wheat imports may be used to support domestic grain producers. The positive production impact must, however, be balanced against the negative effects of P.L. 480 on commercial wheat imports and the potential disruptions of world wheat markets.

Key words: Brazil, multiplier analysis, P.L. 480, wheat.

Although the United States has reduced its participation in food aid since 1972, under the P.L. 480 program, food aid continues to be an important foreign policy tool. In addition to sales at concessional terms under Title I of the P.L. 480 program, the United States contributes to the goals of the 1974 World Food Conference by distributing annually a minimum of 1.3 million tons of food assistance in the form of grants, under Title II of the P.L. 480 program (USDA 1977, p. 5). Other donor countries, such as those in the European Economic Community (EEC), also are increasing their participation in food aid programs. Increasingly, however, the emphasis is on using food aid positively for agricultural development purposes and avoiding detrimental effects on a country's agriculture caused by the introduction of food aid. For this reason, it is important to evaluate the experiences of the P.L. 480 program of the United States in regard to its actual contributions to agricultural development. Toward doing so, this paper attempts to analyze the effects of P.L. 480 Title I wheat imports on Brazil's grain sector.

Brazil's experiences with the P.L. 480 program provides a good case study. First, many of the previous analyses of the effects of P.L. 480 imports on specific recipients have been made for Asian countries, particularly for India (see Blandford and von Plocki; Hatti; Mann; Rogers, Srivastava, Heady; Seevers; and Sen). Brazil's imports of P.L. 480 wheat have, however, been considerable. Total wheat imports, commercial plus P.L. 480, averaged two and one-half times greater than domestic production over the period 1955–70, and P.L. 480, as a percentage of total wheat imports, increased from 24% in 1955–59, to 47% in 1960–64, then decreased to 16% in 1965–69. P.L. 480 imports averaged 28% of total wheat imports and 70% of domestic production from the time the program began in 1954 to 1970, when the P.L. 480 wheat shipments to Brazil ceased.

Second, the institutional arrangement under which Brazil imports wheat and the extensive government intervention in Brazil's grain sector are interesting for understanding possibilities of using food aid for agricultural development purposes. Such intervention also brings out the necessity of specifically including government policies towards the production and consumption of grains and policies affecting the use and distribution of food aid. For example, Rogers, Srivastava, and Heady, in evaluating the effects of P.L. 480 grain imports on India's grain sector, allow for the possibility of distribution of food aid through a lower-priced concessional market. They find that the impact of food aid on prices and production in India is one-tenth the impact shown when not allowing for the possibility.

In addition to allowing for variation in such factors as government pricing and distribution policies when food aid is introduced into an economy, interrelationships in production and

consumption also should be included. This is difficult when all grains are aggregated into a single commodity. The present study includes these interrelationships in production and consumption among four major grains as well as the government policies affecting the production and consumption of these grains. An econometric model including these interrelationships and reflecting the grain-marketing strategies of the Brazilian government is developed, and a multiplier analysis is used to quantify the effects of P.L. 480 Title I wheat imports on grain prices, production, and consumption.

Grain-Pricing Policies in Brazil

The government intervenes extensively in grain pricing in Brazil, particularly for wheat, guaranteeing minimum prices to producers, setting consumer price ceilings and trade restrictions. Since 1952, the Marketing Department for National Wheat (CITRIN) has conducted all purchases and sales of domestic wheat and has been the sole importer and supplier to domestic mills. In 1962, CITRIN became the sole purchaser, at the established support price, of domestic wheat. The imported and domestic wheat is sold to the mills at a uniform price, a price set such that the processed products fit within the purchasing power of the average urban consumer. The price at which the government sells imported and domestic wheat to the millers is generally higher than that which the government paid for the imported wheat, but lower than the established support price which the government pays to the domestic wheat producer (Knight, p. 89; Paiva, Schattan, Freitas, p. 141).

Given a low enough price for imported wheat, there exists an opportunity for the government, through CITRIN, to make revenues from the sale of imported wheat and utilize the revenues gained for subsidizing domestic producers. For example, in figure 1, where P_1 is the price to the mills of domestic and imported wheat, P_2 is the price paid by the government for imported wheat, and P^* the established producer support price, revenues $ABCD$ can be made from selling amount Q_1Q_2 of imported wheat to the mills at price P_1, revenues which can be used to cover the subsidy of P_1 AJP^* paid to producers. This subsidy is the difference between the price, P^*,

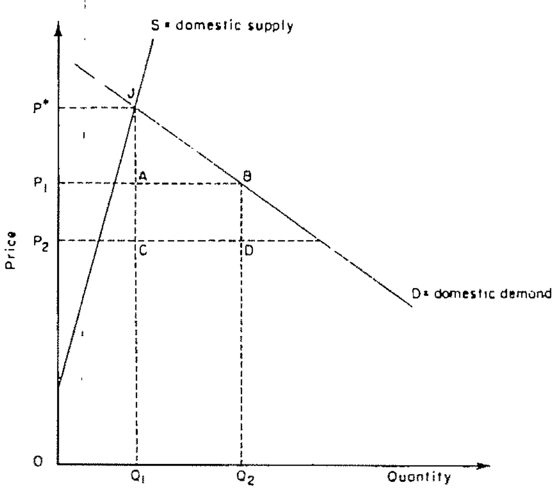

Figure 1. Wheat import revenues and production subsidy costs

paid by the government for the domestic production and the price, P_1, received by the government from its resale. The lower the per unit price paid by the government for imported wheat, the greater the revenues that can be made from importing a given amount of wheat and reselling it at a set price (such as P_1 in fig. 1) to the mills. If the revenues obtained are used to subsidize domestic producers by increasing price supports in, for example, the following time period, the greater the revenues, the greater can be the subsidy to domestic producers. Alternatively, the lower the import price of wheat, the lower can be the price at which the government sells the wheat to the mills (and given constant marketing margins, the lower the price to the ultimate consumer of wheat) and still maintains sufficient revenues to cover the cost of the domestic production subsidy at an established support price (such as P^* in fig. 1). Because the price regulation implied by such strategies is the result of a political balancing of producer and consumer interests, the outcome is not completely determinate, but will vary from year to year.

By importing a greater proportion of wheat under P.L. 480, the average price of wheat imports is considerably decreased. (See Adams et al., Berlage, Dudley and Sandilands, Knight). Government revenues may be increased correspondingly and used in the ways described above. As a rough indication of the extent to which it would have been possible for the Brazilian government to have used the revenues obtained from importing commercial and P.L. 480 wheat, reselling it to the mills at a generally higher price, to cover the costs

of the subsidy to domestic producers (costs incurred by buying domestic wheat at the established price support, and reselling it at a generally lower price to the mills), these revenues were calculated over the period 1955–70. The revenues were calculated in local currency, evaluated at the prevailing exchange rate, assuming (*a*) that the P.L. 480 component of total imports was a pure grant and (*b*) the full c.i.f. price was paid for the P.L. 480 component. Under (*a*), the revenues obtained during each year would have been sufficient to cover the costs of the domestic price support program in twelve of the years from 1955–70, but under assumption (*b*), i.e., no grant element in the P.L. 480 imports, the revenues would have covered those costs in only four of the years, indicating the importance of P.L. 480 in the use of import revenues to support wheat prices.

Econometric Model of Brazil's Grain Sector

To evaluate the effects of P.L. 480 wheat imports on Brazil's grain sector, a simultaneous equation model, incorporating supply and demand relationships for wheat, corn, rice, and soybeans, was formulated, using as a basis the marketing and pricing strategies discussed above. The structural equations of the model, for each grain i, wheat, corn, rice, and soybeans, are

$$(1)\quad A_t^i = f^i(A_{t-1}^i, P_{t-1}^i, P_{t-1}^j, FP_{t-1}, CPI_{t-1}, TR),$$

$$(2)\quad QS_t^i = A_t^i Y_t^i,$$

$$(3)\quad PCQD_t^i = f^i(P_t^i, P_t^j, PCInc, CPI_t),$$

$$(4)\quad PCQD_t^i = \frac{QD_t^i}{N_t}, \text{ and}$$

$$(5)\quad QD_t^i = QS_t^i + M_t^i - Ex_t^i,$$

where t refers to the time period; A^i is area harvested of grain i, in 1,000 hectares (a constant relationship between planted and harvested hectarages was assumed); P^i, the price of grain i, cruzerios per metric ton; P^j, the price of substitute or complementary grain(s) j, cruzerios per metric ton; FP, the price for fertilizer, cruzeiros per metric ton; CPI, the consumer price index, 1963 = 100; Tr, the time trend; QS^i, the total domestic production of grain i, in 1,000 metric tons; Y^i, the average "yield" of grain i, metric tons per hectare (total quantity supplied divided by area harvested); $PCQD^i$, the per capita consumption of grain i, kilograms per capita; $PCInc$, the per capita income, cruzeiros per capita; QD^i, the total consumption of grain i, 1,000 metric tons; N, the total population, millions; M^i, the total commercial imports of grain i, 1,000 metric tons; and E^i, the total exports of grain i, 1,000 metric tons.

Because the current year's wheat support price, the price at which the government will purchase the domestic wheat crop, is set in advance of the planting and harvesting seasons, the support price set for year t would be expected to influence planting decisions in year t. Therefore, in equation (1), where i is wheat, P_{t-1}^i is P^{*w}_t, the domestic support price for wheat in year t.[1] Also, where j is wheat in equation (1), P_{t-1}^j is P^{*w}_t, that is, the current year's wheat support price in year t also influences hectarage decisions in year t for complementary or substitute grains. Lagged fertilizer prices were included as an indication of expectations regarding input prices.

Although minimum prices for rice, corn, and soybeans also have been set by the government, through the Commission for Production Financing (Comissao de Financiamento da Producao, or CFP), these prices cannot be said to have been relevant for production decisions during the time period studied. Minimum prices were usually below market prices and there was limited CFP participation in the market with few purchases exceeding 10% (Paiva, Schattan, Freitas, pp. 150–51). Minimum prices for grains other than wheat then were not used in the hectarage equations.

Where i is wheat in the demand equation (3), P^i was replaced by $\bar{P}^w$, the price at which the government sells the domestic and imported wheat to the mills. Similarly, where j is wheat, P^j is $\bar{P}^w$. Lack of reliable data prevented the demand for grains being expressed as final demands, such as for bread, corn products, etc. Retail demand responses can be generated, however, given constant margin assumptions. (See Foote, pp. 203–04).

All of the price variables are expressed in nominal terms. Leamer and Stern (pp. 45–47) argue that because the absence of money illusion is only a postulate and not a necessary description of reality, the absence of money

[1] Wheat support prices are from Brazilian government *Portarias*, or official decrees, issued closest to harvest date and are based on cost of production plus a profit margin considered sufficient to encourage the desired annual production increase.

illusion is too strong a proposition to be known a priori and imposed on the data. The coefficient on the undeflated price variable may be interpreted as the response of quantity demanded (or supplied) holding all other prices, the consumer price index (CPI), and incomes constant. Where price expectations, represented by lagged prices, were determinants of hectarage decisions, lagged CPI also was used for consistency and may be interpreted as a variable indicating expectations regarding inflation and affecting decisions accordingly.

In addition to the above set of equations (1) through (5), two equations pertaining only to wheat were added:

$$(6) \quad M_t^w = f^w(QS_t^w, P.L.\ 480_t^w, FXR_t, \bar{P}_t^w, CPI_t, Tr), \text{ and}$$

$$(7) \quad P^{*w}_{t+1} = f^w(M_t^w, P.L.\ 480_t^w, IP_t^w, CPI_t, Tr),$$

where M^w is quantity of commercially imported wheat, 1,000 metric tons; $P.L.\ 480^w$ is quantity of P.L. 480 wheat imported, 1,000 metric tons; FXR, foreign exchange reserves, millions of U.S. dollars; IP^w, international price of wheat, U.S. dollars per metric ton, and other variables are as defined above. In addition, $P.L.\ 480_t^w$ was added to the right-hand side of identity (5) for when i is wheat. Unfortunately, stocks could not be included in the model because of data availability.

The basic explanatory variables for the commercial wheat imports equation are suggested by the theory of demand in which the quantity demanded of a good depends on income, own price, and prices of other commodities. If imports and domestic goods are perfect substitutes, as may be approximately supposed for wheat, domestic supply also would be expected to influence directly imports and should be added to import demand. The level of foreign exchange reserves may be particularly relevant to a developing country's decision to import, especially if it is the government which controls imports, as in Brazil. It is likely that imports respond more to foreign exchange availability than to income levels (Leamer and Stern, pp. 15–16) or to the international price. For this reason and because in preliminary ordinary least squares (OLS) estimation the international price of wheat was found to be insignificant,[2] the reserve levels are entered as a determinant of import demand in place of international price and income levels.

Because of the government's control over wheat imports, whereby the imported wheat is sold to the mills at a set price, the mill price, $\bar{P}^w$, is also a determinant of commercial imports. Because of possible substitutions of P.L. 480 for commercial wheat and the role of P.L. 480 in lowering the total cost of wheat imports, the quantity of P.L. 480 wheat imported also determines commercial imports. P.L. 480 is treated as an exogenous variable because the quantity of P.L. 480 wheat to be imported is agreed upon a considerable length of time before actual importation.

The wheat support price equation (7) is based upon the fact that the same government agency sets support prices to wheat producers, importing and reselling imported wheat at a predetermined price to mills, a price usually higher than that paid by the government agency for the imported wheat. As discussed above, the revenues gained by doing so can be used to subsidize domestic wheat producers through higher price supports and the wheat support price is made a function of the determinants of these revenues. The support price in time $t + 1$ is made a function of revenues gained in time t because it is unlikely that the domestic supply schedule is known with great enough accuracy to enable the government to set a price support in time t (determining thereby domestic production and the quantity of imports needed) such that any import revenues made would be sufficient to cover the costs of buying the domestic production at that price support. P^{*w}_{t+1} then is made a function of the amount of commercial wheat imported in time t, the price at which the commercial imports were obtained, and the amount of P.L. 480 wheat imported, since the greater the amount of P.L. 480 in total imports, the lower the total cost of imports and the greater the revenues.

Data Sources and Measurement

Production, area harvested, and yield are from Brazil, Fundacao Instituto Brasileiro de Geografia e Estatistica (FIBGE) and Subsecretaria

[2] $$M_t^w = \underset{(7.20)}{2313.86} - \underset{(6.09)}{.88}\ QS_t^w - \underset{(6.45)}{.82}\ P.L.\ 480_t^w + \underset{(.40)}{.06}\ FXR + \underset{(1.51)}{1.00}\ \bar{P}_t^w + \underset{(.45)}{.49}\ CPI_t + \underset{(.03)}{.13}\ IP_t^w.$$

$R^2 = .93$

t-ratios in parentheses.

de Planejamento e Orcamento (SUPLAN), as are exports and imports and consumption, supplemented with data from the Food and Agriculture Organization (FAO) production and trade yearbooks, and USDA *Reference Tables* FR1-76 and FG9-76 (1976a, b). P.L. 480 shipments of wheat are from U.S. Department of Agriculture, Title I, Public Law 480, and include sales for local currency credit, dollar credit, and convertible local currency credit. Wheat flour was not included in the wheat imports data. Per capita figures were obtained using midyear estimates of population from the International Monetary Fund (IMF).

The support prices for domestically produced wheat are from the Brazilian government *Portarias*, or official decrees, issued closest to harvest data. From 1954–64, the prices are from Brazil, Ministerio da Agricultura and from 1965, are from Brazil, Superintendencia Nacional de Abastecimento. The support price issued for production year 1965–66, for example, refers to the quantity produced in 1966.

The prices paid by the mills for domestic and imported wheat were obtained from government *Portarias*, in which, for example, the 1966 price refers to 1966 consumption figures, and were also obtained from value of production (at farm level) data from FIBGE and SUPLAN, as were the prices for corn, rice, and soybeans. 1974 and 1975 prices for corn and rice are from Brazil, Centro de Estudos Agricolas.

Fertilizer prices are average prices paid in the state of São Paulo, weighted by apparent consumption of nitrogen, phosphate, and potassium fertilizers, from the Instituto de Economia Agricola. The consumer price index, 1963 = 100, is for period averages for the city of Rio de Janeiro, calculated by the Getulio Vargas Foundation, published by IMF, as were foreign exchange reserves of the Bank of Brazil. The international price of wheat used is the FOB Gulf, U.S. No. 2 hard winter, ordinary protein price, from the International Wheat Council.

Estimation

In the above system of equations (1)–(7), there are a total of twenty-two endogenous and twenty-eight exogenous variables, the endogenous variables being for each grain i: A_t^i, QS_t^i, $PCQD_t^i$, P_t^i (where i is wheat, P_t^i is $\bar{P}^w_t$), QD_t^i and, where i is wheat: M_t^w and P^{*w}_{t+1}. The exogenous variables for each grain i are: A_{t-1}^i, Y_t^i, and P_{t-1}^i (or P^{*w}_t, where i is wheat), in addition to FP_{t-1}, CPI_t, IP_t^w, CPI_{t-1}, $PCInc_t$, N_t, $P.L.\ 480_t^w$, FXR, Inc_t, and Tr, and, for when i is not wheat, M_t^i and Ex_t^i.

A stochastic disturbance term was added to all equations, but the identities and the model was estimated over the period 1952–75. Because of the recursive nature of the equations, the hectarage equations and the wheat price support equation for year $t + 1$ could be estimated consistently by OLS. The demand equations and the commercial wheat import equation were estimated by two-stage least squares (TSLS). From the statistical estimation of the model, the reduced form of the system was obtained and multiplier analysis performed.

Validation

To validate the model, from the reduced form, the model was simulated over a fifteen-year time period from the year 1952, and predicted values for wheat production and wheat imports were compared with observed values, although there are methodological difficulties (discussed in Day and Singh) in arriving at proper evaluation criteria. Predicted values closely followed the trends of actual values. Deviations of predicted from actual values averaged less than 21% for wheat production, the most serious deviations being overrepresentations of about 45%, for the years 1958 and 1966. For commercial imports, deviations of predicted from actual values averaged 18%, the most serious being an underrepresentation of 50% in 1964. When it is considered how much variation in wheat production and imports the model had to explain, the average deviations are seen to be moderate.

Results

The results of the hectarage equations estimated by OLS are shown below, with t-ratios in parentheses

$$\begin{aligned} A_t^w = {} & \underset{(2.37)}{531.2001} + \underset{(4.65)}{.7907}\, A_{t-1}^w \\ & + \underset{(2.86)}{6.2281}\, P^{*w}_t - \underset{(2.84)}{3.8054}\, FP_{t-1} \\ & - \underset{(1.33)}{.8117}\, CPI_{t-1} - \underset{(2.88)}{43.7894}\, Tr, \\ R^2 = {} & .90 \qquad D.W. = 2.24 \end{aligned}$$

$$A_t^c = \underset{(2.63)}{2{,}586.7662} + \underset{(1.53)}{.3836}\, A_{t-1}^c + \underset{(.35)}{1.8272}\, P_{t-1}^c + \underset{(3.42)}{8.4091}\, P^{*w}_t - \underset{(2.67)}{5.7680}\, FP_{t-1} - \underset{(2.42)}{2.0807}\, CPI_{t-1} + \underset{(2.46)}{152.6350}\, Tr,$$

$$R^2 = .98 \qquad D.W. = 1.79$$

$$A_t^r = \underset{(2.40)}{819.5296} + \underset{(1.99)}{.4572}\, A_{t-1}^r + \underset{(1.87)}{7.2875}\, P_{t-1}^r + \underset{(1.53)}{3.4364}\, P^{*w}_t - \underset{(1.99)}{8.8027}\, P_{t-1}^c - \underset{(.63)}{1.2358}\, FP_{t-1} - \underset{(2.26)}{2.0072}\, CPI_{t-1} + \underset{(2.20)}{82.7866}\, Tr,$$

$$R^2 = .96 \qquad D.W. = 1.81$$

$$A_t^s = \underset{(1.96)}{-123.9210} + \underset{(.48)}{.1386}\, A_{t-1}^s + \underset{(.37)}{.1710}\, P_{t-1}^s - \underset{(7.48)}{6.8075}\, P^{*w}_t + \underset{(4.72)}{18.2543}\, P_{t-1}^c + \underset{(6.68)}{1.3354}\, CPI_{t-1} + \underset{(3.85)}{28.8212}\, Tr.$$

$$R^2 = .98 \qquad D.W. = 1.74$$

In general, the signs of the coefficients are as expected. The response of corn hectarage to its own price is not significant, and rice area responds negatively to increases in corn prices, both findings made by previous studies also (USDA, June 1975). Corn and rice price elasticities of supply response, although on the low side for corn, are similar in magnitude to those calculated from other studies (see Ramalho de Castro and Schuh).

In the wheat and corn equations, the coefficient for P^{*w}_t is positively significant at the 5% level but is significant at only the 20% level in the riçe equation; removal of the wheat support price from the rice equation made little difference in the estimation results or in the reduced form discussed below. Corn area responds positively to an increase in the wheat support price because of interaction in the feed grain market, whereby as the price of wheat increases, the diversion of the crop to livestock feed is reduced, raising the demand for feed grains, such as corn. Further model development should include a livestock sub-sector to include more thoroughly these interactions.

Soybean area responds negatively and significantly at the 5% level to increases in the wheat support price. Engler and Singh, in an analysis of the impact of changes in the domestic support price of wheat on production and use of resources, found that because of the wheat-soybean double-cropping pattern in the wheat region of Rio Grande do Sul, the major wheat producing state, a wheat support price increase would reduce the relative profitability of soybeans and result in a shift of land use to wheat. In other areas of the country, as in the state of São Paulo, soybeans are grown as a single crop and may substitute more directly with wheat. In making hectarage decisions, soybean producers may respond more readily to the wheat support price than to own price, such that we find an insignificant response of soybean area to its own price in the estimated equation.

The results of the demand equations, estimated by TSLS are shown below, with standard errors in parentheses. (Because the properties of TSLS estimators are asymptotic only, such indications of statistical significance as standard errors are not really meaningful and are given here only because the preliminary OLS estimates of the demand equations were similar to the TSLS estimates.)

$$PCQD_t^w = \underset{(.84)}{38.4282} + \underset{(.02)}{.0261}\, PCInc_t - \underset{(.02)}{.0312}\, \bar{P}^w_t + \underset{(.01)}{.0177}\, P_t^r + \underset{(.01)}{.0036}\, CPI_t,$$

$$D.W. = 1.73$$

$$PCQD_t^c = \underset{(2.78)}{118.2781} + \underset{(.08)}{.0028}\, PCInc_t - \underset{(.09)}{.0900}\, P_t^c + \underset{(.06)}{.0272}\, \bar{P}_t^w + \underset{(.03)}{.0208}\, CPI_t,$$

$$D.W. = 1.62$$

$$PCQD_t^r = \underset{(2.96)}{62.6747} + \underset{(.08)}{.0385}\, PCInc_t - \underset{(.05)}{.0899}\, P_t^r + \underset{(.01)}{.1742}\, \bar{P}_t^w - \underset{(.01)}{.0460}\, CPI_t,$$

$$D.W. = 1.79$$

$$
\begin{aligned}
PCQD_t^s = \underset{(.34)}{.8766} &+ \underset{(.01)}{.0350}\, PCInc_t \\
&+ \underset{(.003)}{.00759}\, P_t^s + \underset{(.007)}{.0463}\, P_t^c \\
&- \underset{(.001)}{.0044}\, CPI_t. \\
D.W. &= 2.07
\end{aligned}
$$

In general, the signs of the coefficients are as expected a priori for all grains except soybeans; this result was obtained with several different formulations of soybean demand response.

The commercial wheat imports (not including P.L. 480) equation M_t^w, estimated by TSLS is, with standard errors in parentheses,

$$
\begin{aligned}
M_t^w = \underset{(177.62)}{2075.4929} &- \underset{(.13)}{.8390}\, QS_t^w \\
&- \underset{(.14)}{.8935}\, P.L.\ 480_t^w + \underset{(.06)}{.1008}\, FXR_t \\
&+ \underset{(1.19)}{2.1811}\, \bar{P}_t^w - \underset{(.74)}{.4558}\, CPI_t \\
&+ \underset{(16.02)}{30.8590}\, Tr. \\
D.W. &= 2.00
\end{aligned}
$$

As expected, as the domestic quantity supplied, QS_t^w, increases, commercial imports decrease. As foreign exchange reserves, FXR_t, increase, commercial imports increase. When the price at which the government sells the wheat to the mills, $\bar{P}_t^w$, increases, commercial imports increase. This would be due to the government's price intervention and its control over the entire wheat importing and domestic resale operations, such that $\bar{P}_t^w$ is not determined solely by market forces but is determined by the government in its revenue-making operations. As $\bar{P}_t^w$ is raised, more wheat may be imported to increase import revenues, perhaps at the expense of domestic production if domestic demand has not shifted outward, or imports may be increased to bring $\bar{P}^w$ down to a level more in keeping with consumer interests, and revenues sacrificed. What is important to note is that the influence of $\bar{P}^w$ on commercial imports is not the result of free market determination, but is the result of the government's separation of producer and consumer prices.

As P.L. 480 wheat imports increase, commercial imports decline, indicating that P.L. 480 imports do substitute for commercial imports. Abbot has also found this substitution effect for countries other than Brazil and Stam has discussed P.L. 480's detrimental effect on Canadian wheat exports. (With perfect substitution, a coefficient of −1 would have been obtained. Alternatively, had the P.L. 480 imports been distributed in such a way as to create additional demand, as was found by Rogers, Srivastava, Heady to have been the case in India, the coefficient on P.L. 480 might have been positive).

The results of the wheat support price equation for time period $t + 1$ estimated by OLS (t-ratios in parentheses) are

$$
\begin{aligned}
P^{*w}_{t+1} = \underset{(1.91)}{-23.6271} &\quad - \underset{(.89)}{.0434}\, M_t^w \\
&+ \underset{(2.27)}{.1361}\, P.L.\ 480_t^w + \underset{(.29)}{.2781}\, IP_t^w \\
&+ \underset{(7.07)}{.6367}\, CPI - \underset{(1.70)}{12.8860}\, Tr. \\
D.W. &= 1.63.
\end{aligned}
$$

As commercial and P.L. 480 wheat imports increase, so does the wheat support price. Depending upon the domestic supply and demand conditions (including the $\bar{P}_t^w$ at which the government sells the imported wheat), as imports increase, the revenues from wheat imports, and the support price formed in time t + 1 from these revenues, may increase. P.L. 480, in reducing the cost of total imports, contributes to increased revenues and increased support prices. Or, the increase in imports may prompt the government to raise the domestic support price in an attempt to reach self-sufficiency and decrease reliance on imports, particularly upon commercial imports which use scarce foreign exchange reserves, this also being a probable reason for the positive coefficient on international price.

Multiplier Analysis and Interpretation

The reduced form of the simultaneous equation system (1)–(7) was obtained, using linear approximation procedures described by Womack and Matthews. Only the relevant elements of the coefficients of the reduced form, π_1, and π_2, are shown in table 1, with the endogenous variables of the model on the far left-hand side of the table and a partial listing of the predetermined variables along the uppermost row of the table.[3]

[3] *PCInc* is shown in the reduced form of table 1 as an endogenous variable because it was linearized as a quotient of two other exogenous variables, total income and population.

Table 1. Brazil: Reduced Form

	Predetermined										
					Π_1					Π_2

QS_t^s								.2172			23.

The initial impacts of a unit increase of 1,000 metric tons of P.L. 480 wheat during a single time period can be seen under the column variable, P.L. 480, in π_2. Of a total increase of 1,000 metric tons of P.L. 480 wheat, only about 19% or .00243 kilograms per capita, is reflected in a net increase in wheat consumption (fifteenth row). Such a small increase in net consumption occurs because 80% of the unit increase in P.L. 480 results in a displacement of commercial imports (tenth row).

The impacts on grain prices are not large. The price at which the government sells wheat to the mills, $\bar{P}_t^w$, increases by .0137 units, or 13 cruzeiros (fifth row), as would be expected from the intervention of the Brazilian government in the pricing system. The impact of P.L. 480 on $\bar{P}_t^w$ includes P.L. 480's direct effects on $\bar{P}_t^w$, $\bar{P}_t^w$ being increased as a result of the government's attempts either to increase import revenues or to keep them at a constant level when the price of commercial imports increases, and P.L. 480's indirect effects on $\bar{P}_t^w$, i.e., through P.L. 480's negative effects on commercial imports and the corresponding increase in consumer prices which may be implied.

The reduced form also shows, as a result of demand interactions among grains, increases in corn and rice prices—by .00415 units, or 4 cruzeiros and .02655, or about 26 cruzeiros, respectively, and a decrease in soybean price—by .02533 units or 25 cruzeiros. There is a very small impact (negligible enough to be ignored) on consumption of grains other than wheat. Even given small price impacts of P.L. 480, negligible consumption effects could result if substitutions among grains due to price changes canceled consumption impacts. It is also possible that consumption effects are not adequately represented, perhaps due to the linearization of the demand equations needed for the reduced form. However, the impact of P.L. 480 on the next period's wheat support price, P^{*w}_{t+1}, is positive—an increase of 1,000 metric tons of P.L. 480 wheat increases the wheat support price by .10096 units or 100 cruzeiros.

The delay multipliers (table 2) indicate the impact of P.L. 480 during successive time periods, and because of the use of lagged price in the area response equations, are used to evaluate the production effects of P.L. 480. There is an initially positive impact of P.L. 480 wheat imports on wheat, corn, and rice production in the first time period after the initial change (year one), with the effects declining over time and in an oscillatory fashion for wheat and corn. An increase of 1,000 metric tons of P.L. 480 wheat leads to an increase of 500 metric

Table 2. Brazil: Production Multipliers

Year	Wheat	Corn	Rice	Soybeans
		Delay Multipliers		
1	.50121	.00998	.29430	−.00550
2	−.06192	−.00799	.18214	−.00201
3	.00765	.00640	.11236	−.00073
4	−.00012	−.00410	.04318	−.00010
5	.00000	.00169	.00633	−.00009
6		−.00029	.00014	−.00000
7		.00001	.00000	
8		.00000		
		Cumulative Multipliers		
1	.50121	.00998	.29430	−.00550
2	.43929	.00199	.47645	−.00751
3	.44693	.00839	.58881	−.00824
4	.44682	.00428	.63198	−.00833
5	.44682	.00597	.63832	−.00834
6		.00569	.63846	−.00834
7		.00569	.63846	

tons of domestic wheat in the first year, its effects declining rapidly thereafter. Also shown is an increase of about 9 metric tons of corn in the first year, with zero effect in the eighth year and an increase of 294 metric tons of domestic rice production, which declines until reaching zero in the seventh period. The impact on soybean production is mildly negative in the first time period and in successive periods; there is an initial decline of about 5 metric tons of domestic production, the effect reaching zero in the fifth year.

The cumulative multipliers show the effect of a sustained unit increase of P.L. 480 wheat over time (table 2). The point at which the value of the cumulative multiplier reaches a stable value, defined to a particular decimal place, is the long-run multiplier and for wheat, corn, and rice are .447, .0056, and .638. That is, a sustained increase of 1,000 metric tons of P.L. 480 wheat would result in increased domestic production of 447 metric tons of wheat in five years, of about 5 metric tons of corn in seven years, and of 638 metric tons of rice in seven years; it would also result in a decrease of eight metric tons of soybeans in six years. The net effect of a sustained increase of 1,000 metric tons of P.L. 480 wheat imports then would be to increase domestic grain production by 108% (obtained by totalling the long-run multipliers of each grain and dividing by 1,000).

It is stressed that the model and reduced form results pertain to the grain sector of the entire country, although much of the wheat production is concentrated in Rio Grande do Sul, which accounted for some 67% of the area sown to wheat in 1970. In this region, production substitutions were primarily between wheat and pastureland for cattle. (See Knight and Singh and Ahn.) However, wheat production has been increasing in other areas of the country—as in the state of Sao Paulo, where wheat production, averaging only a little more than 4,000 metric tons during the 1960s, grew to 74,000 metric tons in 1974. Here, there was little competition between crops and cattle grazing for the use of land; area in pasture increased in the regions of the state where cropland increased and decreased in the regions where cropland decreased (USDA, June 1975, p. 24). It was felt, therefore, that a countrywide model, as opposed to a regional model, would better include this diversity and would be needed to obtain a better measure of the overall impact of P.L. 480 imports; this countrywide model should provide an interesting comparison to a regional model.

Conclusions

On the basis of the above results obtained from a model of Brazil's grain sector, which included demand and supply interrelationships among the grains and specific government intervention policies in the importing and the domestic marketing of wheat, it appears that Brazil has managed to use P.L. 480 wheat imports in a beneficial way for domestic production. Primarily because of the use of revenues from wheat imports to encourage production by supporting the price to domestic wheat producers, wheat production has tripled from 1952–71, and has increased from 30% to 53% of total consumption.

On the other hand, the results also show that P.L. 480 imports have displaced commercial wheat imports, in spite of the Usual Marketing Requirements imposed, and this disruption of international commercial wheat markets has obvious implications for third-country wheat exporters.

Wheat Acreage Supply Response under Changing Farm Programs

B. J. Morzuch, R. D. Weaver, and P. G. Helmberger

Planted wheat acreage supply elasticities are estimated for each of several leading wheat-producing states. Estimates of elasticities for the aggregate of these states are 0.77, 0.45, and 0.52 for spring wheat, winter wheat, and all wheat, respectively, but there is considerable heterogeneity among states. Acreage allotments and marketing quotas appear to have destroyed the role of prices in allocating acreage between wheat and other crops during the years 1950 and 1954–64. Estimates were obtained using multiple regression analysis of time-series data for the period 1948–74. This period was subdivided in order to take account of changing farm programs.

Key words: farm programs, regression analysis, supply elasticities, wheat acreage.

In their survey of agricultural price analysis, Tomek and Robinson call attention to the difficulties encountered in supply analysis and to the inadequacy of the elasticity estimates currently available. Supply estimation is particularly difficult for major commodities subject to farm programs. These programs change every three to five years and tend to complicate supply estimation because relevant variables and structural parameters may change over time. While supply equations must be conceptualized under alternative policy regimes, conserving degrees of freedom often necessitates approximations that are difficult to justify on strictly a priori grounds.

The need for good estimates of supply elasticities is great, however, and researchers continue to experiment with alternative approaches. Developing outlook information, predicting the consequences of proposed changes in farm policy, analyzing the welfare implications of commodity storage, and quantification of spatial equilibrium models are examples of research areas that require estimates of supply elasticities.

The purpose of this paper is to present the main results of an analysis of wheat acreage supply response. Unlike other studies of wheat supply, this study uses futures prices as a proxy for expected prices for wheat and competing crops. A different acreage response equation is conceptualized for each of three periods since World War II in light of changing farm programs for wheat. Supply equations are estimated for each of several major wheat states rather than for the nation as a whole. A considerable effort was made to measure all variables with as much precision as possible.

Our estimates of structural parameters support the following conclusions. First, during the years when acreage allotments and marketing quotas were not in effect, the response of wheat acreage to the price of wheat relative to prices of competing crops was larger than previous supply estimates would suggest. Second, there is a considerable heterogeneity in supply response among major wheat-producing states. Third, farm policy during the "quota years" appears likely to have destroyed the role of price in allocating acreage between wheat and competing crops. Finally, the voluntary nature and substitution and other provisions of programs beginning in the mid-sixties restored an allocative role to wheat price not unlike that under "free market" conditions. It appears that policy changes introduced in the sixties were quite successful in

making greater use of the market mechanism in resource allocation.

Our analysis draws upon previous work in several important respects, but, at the same time, questions some existing research procedures and results. Gardner has proposed using futures prices as proxies for expected prices; our findings lend further support for this thesis. To take account of farm programs Lidman and Bawden inserted several program variables in a regression equation, giving little attention to the modeling of producer decision making in the face of changing programs over time. Garst and Miller improved upon the Lidman and Bawden work, in effect allowing new variables to appear (disappear) and parameters to change as programs varied. Their decision to include land diversion and set-asides as independent variables is of some concern, however, in that decisions to plant and divert are made simultaneously. Some of their independent variables may be endogenous, thus raising the question of simultaneous equations bias. We return to this issue later. Garst and Miller and Houck et al. insert price as an independent variable, but price is not expressed relative to the prices of competing crops. Their procedure receives little support from economic theory. Unlike the previous works of Garst and Miller, Lidman and Bawden, and Houck et al., we do not assume that wheat acreage supply elasticities are the same for quota and nonquota years. As a final preliminary, the decision to disaggregate supply analysis to the state level stands in contrast to previous work and allows greater accuracy in the definition of variables. For instance, Lidman and Bawden divided lagged U.S. wheat price by a lagged U.S. index of feed grain and hay prices received by farmers. This index is dominated by U.S. corn prices which, while quite appropriate for wheat producers in the Corn Belt, would seem to be much less so for wheat producers in the plains states.

Conceptualizing Acreage Response Functions under Alternative Policies

In major wheat-producing areas, farmers have flexible production capacity that can be used to produce various crops other than wheat, including feed grains, rye, soybeans, flax, etc. We assume that producers allocate acreage among competing crops to maximize expected profit.[1] Under free market conditions, acreage planted to wheat may be viewed as a function of expected crop prices, exogenous input prices, variables measuring climatic expectations and endowments, the nature and extent of fixed-scale factors, and the current state of technology. Such a relationship is merely one among several reduced-form relationships, others being those for output, inputs other than acreage, and endogenous input prices (Weaver 1978). In addition, theory of the firm suggests that the function in question is homogenous of degree zero in prices; and increase in all prices will have no impact on planting decisions. This suggests that farmers are concerned with relative expected crop prices in allocating acreage among competing crops and would not respond to a proportional change in all expected prices. Although this point would seem clear even on an intuitive basis, typical acreage response functions estimated in the past have not been restricted to be linearly homogenous in prices.

A simple wheat acreage response function may be hypothesized under these conditions as follows:

$$(1)\quad WAP = \alpha_0 + \alpha_1\, ERP + \alpha_2\, TREND + \epsilon,$$

where WAP represents acreage planted to wheat; ERP represents the expected relative price, i.e., the expected price of wheat divided by an index of expected prices for competing crops; $TREND$ is self-explanatory; and ϵ is a stochastic term. $TREND$ is inserted to capture the effects of omitted variables that may have exerted systematic effects over time. For example, if technological change has tended to increase wheat yields less rapidly than the yields for competing crops, then for a given ERP, acreage planted to wheat would likely decline. In this study, equation (1) is hypothesized for each of the several major wheat-producing states with the variables defined accordingly. Because equation (1) makes no provision for farm programs, it is hypothesized for those years during which no programs were in effect. These "free market" years consisted of 1948, '49, '51, '52, '53, and 1974. We argue, however, that with suitable modifications, equation (1) may also be appropriate for the years 1965–73.

[1] Similar results undoubtedly would follow from a model of risk-averse choice. However, where risk measures are independent of expectations, exclusions of these variables will not bias our results.

The wheat programs for 1965–70 were voluntary (see Cochrane and Ryan). Wheat producers were awarded direct payments if they abided by their allotments and idled specified minimum percentages of their acreage allotments. Land diversion was not used in 1967 and 1968, but for the other years (1965, '66, '69, and 1970) land beyond the minimum diversions could be idled for additional payments. Wheat producers also were required to maintain normal acreages in conservation uses. Price supports through the nonrecourse loan system still were available to participants, but at greatly reduced levels relative to earlier years. The strategy of the new programs was aimed at allowing wheat output to be marketed through normal commercial channels. Of considerable relevance to the present study were the so-called substitution provisions included in both the wheat and feed grain programs. The feed grain program was similar in essential respects to that for wheat. Farmers who participated in both the wheat and feed grain programs could substitute acreage of feed grains for wheat, or wheat acreage for feed grains, within the total acreage permitted under both programs. A similar provision was open to the producer who had an oat-rye acreage base and was willing to divert some of that base to conservation uses. Wheat could be planted on the oat-rye base acreage. Finally, an overplanting provision allowed the producer to overplant up to 50% of the farm's permitted wheat acreage. The excess production had to be stored under bond, but could be marketed in future years under certain specified conditions. The substitution and storage provisions together with the voluntary nature of the program allowed considerable room for farmers to allocate acreage among competing crops on the basis of expected prices.

Relative to the 1965–70 programs those for 1971, '72, and '73 constituted an even smaller encumbrance on the allocative role of crop prices. Under the wheat and feed grain setaside programs for the latter three years, acreage diversion (set-aside) was required under most options in return for eligibility for direct payments. All remaining land, with the exception of a conserving base, could be allocated among crops in any way the farmer chose. The option of voluntary diversion of cropland beyond minimum diversions for additional payments was also available to feed grain producers in 1972 and to wheat producers in 1972 and 1973.

The above discussion indicates that wheat producers had considerable leeway in allocating land among competing crops over the period 1965–73. Farm programs served mainly to provide farmers with another cropland alternative, viz., the diversion of land for direct payments and other benefits. A wheat acreage response function may be hypothesized under these conditions as follows:

$$(2) \quad WAP = \gamma_0 + \gamma_1\, ERP + \gamma_2\, TREND + \gamma_3\, RUDC + \gamma_4\, MAXD + e,$$

where *ERP* and *TREND* are as explained above, *RUDC* equals an estimated diversion payment per bushel divided by the index of expected prices for all other crops, and *MAXD* equals the upper limit on the extent of permissible land diversion. The homogeneity condition for returns to land diverted is maintained as in the case for returns to land planted to wheat. It is hypothesized that γ_3 is negative in that the higher the relative diversion payment rate, the more land would be diverted and the less land would be planted to wheat. It is hypothesized that γ_4 is negative in that to the extent *MAXD* was actually binding, raising its value would have the effect of increasing land diversion (Weaver 1978a).

In order to conserve degrees of freedom we assume that $\alpha_0 = \gamma_0$, $\alpha_1 = \gamma_1$, and $\alpha_2 = \gamma_2$. This allows using data for the "free market" years along with data for the years 1965–73 for estimating the parameters of equation (2). The two variables *RUDC* and *MAXD* are set equal to zero for the "free market" years, a procedure that disallows acreage diversion during those years. Importantly, we are assuming that the acreage supply equation has the same slope for "free market" years as it did during the "land diversion" years. We also assume that the coefficients for *RUDC* and *MAXD* are the same for 1965–70 as for 1971–73. These are restrictive hypotheses which, given a sufficiently large sample, could be subjected to empirical testing. It should be stressed, however, that our hypothesis regarding slopes is much less restrictive than that maintained by previous supply analysts who have assumed constant supply slopes between quota and nonquota years. To this matter we now turn.

Beginning in 1954 and continuing through 1963, the wheat program involved price supports, acreage allotments, and marketing quotas. Producers who did not exceed their wheat acreage allotments could place their production under nonrecourse loans which in-

cluded price support. They were, therefore, guaranteed a minimum price for wheat. Farmers who exceeded allotments and failed to store their excess production were subject to a penalty tax on the excess marketed. For each acre planted (harvested, after 1955) in excess of the allotment, the producer was required by law to pay a tax equal to the product of his weighted average yield over the previous three years and a per bushel tax. In addition, for some years the future allotment was reduced for the farmer who did not comply with his current allotment. After 1957, noncommercial wheat farmers could harvest thirty acres without penalty so long as the output was fed on the farm. Farmers who planted not more than fifteen acres of wheat were exempt from marketing quota penalties, a provision that was attractive to many farmers in the Corn Belt who were not mainly wheat producers.

Given a package of specific program parameters (allotments, penalties, and price supports) various responses by producers could be rationalized. Agricultural Stabilization and Conservation Service data show that in major wheat-producing states there was widespread compliance with allotments. If penalties were sufficiently onerous and all allotments were actually binding, then acreage allotment alone would determine planted (or harvested) wheat acreage, subject to the exception of land diversion programs to be discussed in a moment, and there would be no basis for including *ERP* as a relevant variable. In other words, the conventional concept of an upward-sloping supply simply would not apply. Hadwiger (p. 197) argues, however, that "during the Benson administration, program rules came to be structured somewhat more in favor of the noncompliers or violators, to the point where the advantage for many producers seemed definitely to be in noncompliance with the program." He further notes that in 1960, the last year of the Benson reign, "43.1 million acres of wheat were in compliance on a total allotment of 50.6 million acres" (p. 194). The 15-acre exemption, the "wheat-for-feed" exemption, and other provisions indicate that the relative price of wheat might be a relevant variable in determining wheat acreage. On balance we are inclined to include *ERP* as an independent variable, but with the expectation that its coefficient is likely to be a good deal less than for the nonquota years and might in fact equal zero.

The wheat program for 1950 involved acreage allotments. Farmers who exceeded allotments paid no penalties but lost price supports. Penalties also were dropped in 1964, although allotments and loss of allotment history were maintained. Importantly, there were no substitution provisions in either 1950 or 1964. For this reason, these two years were included in the "quota years."

In addition to direct acreage controls, land diversion opportunities were offered to producers during many of the quota years. These programs required that the allotment be reduced by the number of acres diverted. Land diversion introduced an alternative use of the allotted wheat acreage, which was constrained by a maximum allowable diversion (*MAXD*) and encouraged by a per bushel incentive equal to a percentage (*PERRU*) times the loan rate.

The acreage supply response hypothesized for the quota years is

$$(3)\quad WAP = \beta_0 + \beta_1\, ERP + \beta_2\, WAL + \beta_3\, PERRU + \beta_4\, MAXD + \mu,$$

where *WAL* equals the wheat acreage allotment, μ is a stochastic term, and remaining variables are as defined previously. Dividing the per bushel payment for land diversion by the loan rate is equivalent to using *PERRU* and again invokes the homogeneity condition in that only those producers who complied with allotments were eligible to participate in land diversion programs. Because the sample period spans only fifteen years and the number of observations is limited, trend was excluded from (3). It is hypothesized that β_1 and β_2 are positive and β_3 and β_4 are negative.

Data

Acreages. The spring wheat states in this study are North Dakota, South Dakota, and Montana. For any one year during the sample period, these three states accounted for a minimum of 76% of U.S. spring wheat production. The winter wheat states are Colorado, Illinois, Indiana, Kansas, Montana, Nebraska, Ohio, Oklahoma, Texas, and Washington. For any one year, these ten states accounted for a minimum of 78% of U.S. winter wheat production. For the spring wheat equations, acreage consists of acres planted to both durum wheat and other spring wheat. The acreage data are taken from various issues of *Crop Production-Revised Estimates* and of *Field Crops-Revised Estimates by States,* both

series published by the U.S. Department of Agriculture (USDA).[2]

Prices. The expected prices for durum wheat and for other spring wheat are measured by the closing futures prices for the two kinds of wheat at Minneapolis on 15 April for the contract delivery month of September. The expected prices for certain other commodities were measured in an analogous fashion. Closing futures prices and contract delivery months were matched with planting dates and harvest dates, respectively, using data from *Usual Planting and Harvesting Dates,* USDA. For all winter wheat states, the closing futures prices on 30 September for delivery in July were used. Chicago quotations were used for soft winter wheat, oats, soybeans, and corn for grain. Kansas City and Minneapolis quotations were used for hard winter wheat and rye, respectively. Winnipeg quotations were used for barley and flax. The futures prices were taken from various issues of the *Wall Street Journal* for the period 1948–74.

Futures prices are unavailable for a number of crops grown in the twelve states. These include hay, sugarbeets, corn for silage and forage, sorghum for grain, forage and silage, potatoes, edible beans, edible peas, mung beans, rice, peanuts, popcorn, cotton, clover, broomcorn, buckwheat, and cowpeas. One-period lagged prices for these crops were chosen as a proxy for the unobtainable futures prices in the construction of an appropriate other crops price index corresponding to either winter wheat or spring wheat. Price information for most crops was taken from various issues of the USDA's *Agricultural Statistics* and *Crop Values*. Prices for crops such as hay, corn for silage and forage, and sorghum for silage and forage were estimated with the assistance of the Statistical Reporting Service, USDA.

A spring wheat price index, its corresponding other crop price index, a winter wheat price index, and its corresponding other crop price index, were derived using Divisia weights. This approach differs from the Paashe or Lespeyres approach in that the weights used by the latter two consist of a given base period weight, whereas the Divisia approach uses weights that change from year to year. The attractiveness of the Divisia scheme lies in its use of changing weights that in turn reflect the changing importance of commodities in terms of both their prices and quantities produced (Tornquist). The quantities used in the formation of these indices were the production figures associated with each crop. The sources of data on production are the same as for wheat acreages.

Government programs. The sum of the domestic marketing certificate and export marketing certificate values for wheat was used as the estimated diversion payment per bushel for 1965. The domestic marketing certificate value and the marketing certificate payment rate were used, respectively, for the periods 1966–70 and 1971–73. These data are taken from *Wheat-1978 Program*, USDA. Data on wheat acreage allotments, diverted acres, percentages of allotments used in figuring maxima for diverted acreages, and the percentages of loan rates used in figuring diversion payments during the quota years are taken from various issues of *Wheat Situation,* published by the USDA, and from Cochrane and Ryan.

Empirical Results

Where contemporaneous correlation exists among the error terms in a set of equations, generalized least squares (GLS) estimation of all equations taken together yields more efficient estimates than does ordinary least squares (OLS) estimation of each equation separately (Kmenta, pp. 517–29). Because of number of observations available and the number of parameters to be estimated there were insufficient degrees of freedom for GLS to be used.

Equations (2) and (3) were estimated by OLS for spring wheat in three states and winter wheat in ten states for the period 1948–74. Estimates for equation (2) are given in table 1. These estimates indicate that acreage planted to wheat was quite responsive to the relative price of wheat in nonquota years. The estimated coefficients for *ERP* are positive in all cases. The t-ratios range from 0.42 to 6.62 and exceed 1.8, the critical value at the 5% level of significance using a one-tailed test, in eight of the thirteen cases. Where the Durbin-Watson (D-W) statistics are low (e.g., Montana and Colorado), t-ratios are probably high.

Price elasticities vary considerably across states. Elasticities range from 0.61 to 0.95 for

[2] Interested readers may write to the senior author for data used in the analysis.

[a] The dependent variable is acreage planted to spring wheat (North and South Dakota, Montana) or to winter wheat (remaining states including Montana); *CONST* is the constant term; *ERP* is the ratio of the expected price of wheat to the index of expected prices for other crops; *TREND* has gaps for missing years; *RUDC* is the ratio of the diversion payment per bushel to the index of expected prices for crops other than wheat; and *MAXD* is maximum allowable acreage diversion. See text for details.
[b] Spring wheat.
[c] Winter wheat.

the three Corn Belt states and from 0.22 to 0.46 for the remaining winter wheat states. This is not too surprising in that one might expect an inverse relationship between extent of specialization and elasticity of acreage response. Acreage elasticities were relatively high for North and South Dakota. It may be noted that the spring wheat states tend to be less specialized than major winter wheat states.

Aggregate supply elasticities were estimated as weighted averages using mean acreages for individual states as weights. Montana was excluded. (In much of our statistical work, the estimates for Montana were neither consistent with expectations nor with the results for other states.) The aggregate acreage supply elasticities for spring wheat, winter wheat, and all wheat combined are 0.77, 0.45, and 0.52, respectively. Previous acreage supply elasticities by Garst and Miller (p. 34) for spring, winter, and all wheat are 0.04, 0.19, and 0.17, respectively. The elasticity reported by Houck et al. (p. 37) equalled 0.39. Over the period 1954–70, Lidman and Bawden (p. 331) found that lagged wheat price was not significant in explaining acres planted to wheat. In most of their formulations the estimated coefficient for price was, in fact, negative.

Although the estimated coefficients for *RUDC* and *MAXD* tend to be negative, as expected, the t-ratios are low. Yet we know that substantial acreages were diverted under major programs during the period 1965–73, and it would seem strange indeed if these idled acres did not reduce at least to some extent acreage planted to wheat. The low t-ratios may be the result of the high levels of correlation observed between *RUDC* and *MAXD*. Moreover, it may well be that the land diversion programs in question were too complex to be represented adequately by the inclusion of

[a] All variables are defined as in table 1 except *DIV* equals acreage diverted under both the wheat and feed grain programs. See text for details.
[b] Spring wheat.
[c] Winter wheat.

but two variables. For example, the two program variables do not take account of minimum diversion, payment rates for additional diversion, allotments, and several other program details that were likely of some importance in determining planted wheat acreage. While further work on this problem may be useful, the number of observations is limited in light of the number of parameters that might require estimation in models more complicated than those considered here.

As part of our exploration, equation (1) was modified by the inclusion of diverted acres (*DIV*) as an independent variable. The variable *DIV* equals the land diverted under both the feed grain and wheat programs and was zero for the free market years and nonzero for the years 1965–73. As noted previously, including *DIV* as an independent variable risks simultaneous equations bias in that diverted and planted acreages are probably endogenous in any reasonable model of producer decision making.

Alternatively, the estimates of equation (1) modified by including *DIV* may be unbiased if it is assumed that the expected value of the dependent variable is conditional on all independent variables including *DIV*.[3] On this interpretation, applicable to the estimates discussed below much as it is to the previous results of Garst and Miller, the estimated equation can be used only in prediction if knowledge of an estimate of the extent of land diversion is available prior to planting times. Clearly this approach, aside from problems of application, is less powerful than one which involves estimation of the reduced forms of a structural model.

Estimates of equation (1) modified by the inclusion of *DIV* are given in table 2. Again, the results for *ERP* are impressive judged by the usual economic statistical criteria. The associated aggregate acreage supply elasticities, again excluding Montana, are 0.90, 0.32, and 0.46 for spring wheat, winter wheat, and all

[3] For a presentation of the relevant theorems and a brief critique, see Malinvaud (pp. 614–17).

[a] The dependent variables, *ERP*, and *MAXD* are the same as in table 1. *CONST* is the constant term; *WAL* is the wheat acreage allotment; and *PERRU* is the percentage of the loan rate used in figuring diversion payments. See text for details.
[b] Spring wheat.
[c] Winter wheat.

wheat, respectively. The estimated coefficients for *DIV* are negative in all cases except for spring wheat in Montana. The t-ratios tend to be small, but the pattern of results across states seems encouraging and the magnitudes of the estimates appear reasonable. Thus, for example, for every 100 acres diverted under the wheat and feed grain programs, the acreage planted to wheat fell by twenty-two acres in North Dakota and twenty-six acres in Kansas. The estimated coefficients are strikingly similar for Nebraska, Oklahoma, Texas, and Colorado.

Turning to the quota years, the estimates for equation (3) are given in table 3. The importance of wheat allotments in determining planted wheat acreage during the quota years is remarkable. Excluding winter wheat in Montana, the estimated coefficients for wheat allotments (*WAL*) are positive for the remaining twelve cases. For eight of these twelve cases the t-ratios for *WAL* exceed 3.0. For several states the estimated coefficient is close to unity, indicating that a one acre increase in allotments was associated with a one acre increase in planted acreage.

A second conclusion is that acreage planted to wheat did not respond positively to the relative price of wheat. The coefficients for *ERP* are negative in every case except one. The t-ratios are low in the majority of cases. Simple correlation coefficients between *ERP* and each of the program variables were very low with only a few exceptions. Adding trend to the equation does not alter the pattern of unexpected signs for *ERP*. These findings may reflect the downward movement of the national average support price for wheat (loan rate) from $2.24 per bushel in 1954 to $1.30 in 1964. The negative sign for *ERP* may reflect an empirical regularity growing out of the evolution of farm policy. In any event, the hypothesis, implicit in previous work, that the acreage supply function during the quota years has the same slope as during the nonquota years would appear to have received a near-fatal blow.

Finally, although the estimated coefficients

for *MAXD* have the expected signs in most cases, the same cannot be said for *PERRU*. While we are unable to explain these results it is possible that the high correlation between *PERRU* and *MAXD* prohibited measuring the separate effects of each with much precision. On balance, however, the findings do not lend much support to the view that diversion programs reduced significantly the acreage planted to wheat during the quota years. This conclusion was also supported by further statistical work in which *MAXD* and *PERRU* were deleted from (3) and a land diversion variable was added in their place. In the revised formulation, the estimated coefficients for land diversion were negative in seven cases and positive in six. Once again, the estimated coefficients for *ERP* were mostly negative.

Implications for Future Work

Three suggestions for future supply analysis may be offered on the basis of findings discussed above. First, futures prices appear to merit consideration as an alternative to using distributed lags in modeling price expectations for economic research. Second, spatial heterogeneity and the opportunity for measuring variables with greater precision might well make disaggregation at least to the state level well worth the extra costs of data collection and analysis. Third, because farm programs change over time and may have profound impacts on the nature of supply response, it is important to structure analysis to allow for changes in relevant variables and in parameters, including elasticities, over sample periods.

The Structure of Production and the Derived Demand for Inputs in Canadian Agriculture

Ramon E. Lopez

The evidence suggests that an aggregate cost function and, hence, an aggregate production function for Canadian agriculture exists. Furthermore, growth in Canadian agriculture has been primarily associated with economies of scale rather than with factor-augmenting technical change. A nonhomothetic dual cost function is used to derive explicitly the system of four input demand equations (labor, capital, land and structures, and intermediate inputs) using time-series data for the period 1946–77. Estimates of the own-price elasticities and of the Hicks-Allen elasticities of substitution among the input pairs are also provided.

Key words: aggregate production function, Canada, cost function, elasticities of substitution, factor-augmenting technical change, input demand.

The purpose of this paper is to present an analysis of the structure of the Canadian agricultural production sector and its derived demand for inputs. Specifically, the emphasis is placed on the following aspects: (*a*) Estimation of a set of aggregate input demand functions and a test of whether or not these functions can be considered to reflect aggregate dual cost and production functions. In short, the aim is to test whether the estimated derived-demand functions satisfy the integrability conditions (Varian, Hurwicz and Uzawa) and, hence, whether an aggregate technology for Canadian agriculture exists. (*b*) Estimation of factor substitution possibilities (or complementarities) and in particular to test formally the hypothesis of fixed coefficients of production in Canadian agriculture. (*c*) Testing for homotheticity of the production function, in particular, whether the production function exhibits constant returns to scale. (*d*) Testing for the existence of factor-augmenting technical change.

The present study differs from previous ones of agricultural production and input demand functions in two respects. First, previous studies have explicitly derived the aggregate input demand functions and estimated them from a cost-minimizing scheme; but they have not been generally concerned whether the estimated demand functions satisfy the integrability conditions.[1] They have not addressed the following question: given a system of estimated aggregate derived-demand equations, is there necessarily an aggregate production function from which the system can be derived? Hurwicz and Uzawa have shown that a system of demand equations is integrable if, and only if, the Hessian matrix is symmetric. But the symmetric Hessian matrix means that the matrix of second partial derivatives of the cost function must be symmetric, and hence, we first test rather than impose the symmetry conditions on our demand system. If the symmetry condition is rejected, it means there does not exist an aggregate cost function and a production function underlying the input demand functions. On the other hand, if the symmetry conditions hold, it implies that the demand functions are integrable to some macrofunction. However, according to Hurwicz, symmetry implies mathematical integrability, but not necessarily economic integrability. Economic integrability of compensated de-

The author wishes to thank A. Woodland, E. Diewert, J. MacMillan, and two anonymous reviewers for their comments. The research assistance of J. Tyson and D. Quan is acknowledged.

[1] Binswanger (1974a) did test for symmetry.

rived-demand functions also means that the function yielded by the integration process (the macrofunction) satisfies the conditions of a cost function, i.e., negative semidefiniteness of the Hessian matrix, with respect to prices, nonnegativity, and nondecreasing in output levels. Accordingly, apart from the symmetry test we will check whether these properties are satisfied by the macrofunction underlying the derived-demand functions.

Second, the functional form used for the cost function is more general than those used by Kako and Binswanger (1974a and 1974b) and it allows for a rigorous test for a fixed-proportion production function as well as for the hypothesis of constant returns to scale and homotheticity. This functional form was used by Woodland in a study of substitution structures at a more aggregate level than ours and applied to all major industrial divisions in Canada. The function used allows simultaneous testing for constant returns to scale and factor-augmenting technical progress. Binswanger (1974b) has been able to separate the effect of biased technical change on the observed factor shares from the effect of ordinary factor substitution due to factor price changes. However, factor shares also can be affected by changes in the scale of production if the production function is nonhomothetic. Binswanger assumed a homothetic production technology, and, hence, he explained all changes in factor shares by fluctuations in factor prices and/or technological change bias. Using our more general functional form, we are able to separate and identify the effects of price changes, factor-augmenting technological change, and production levels in factor demands. Kako also assumed constant returns to scale; and, although he measured technical change biases, he did not rigorously test for neutral or biased technical change.

Following Woodland and others, we assume throughout this paper that input prices are determined in the nonagricultural sectors. This assumption appears reasonable for all inputs with the exception perhaps of land. Agriculture is a major user of the latter input, and hence its price may be endogenous. While it would be desirable to consider the endogeneity of land prices, to do so would increase the number of parameters to be estimated and add complexity to an already difficult model. The assumption that the wage rate is exogenously determined may be dubious. However, according to Lopez and MacMillan, the farm wage rate essentially follows the pattern of nonagricultural wage rates.

The Model

Diewert (1974) has shown that if there exists a continuous from above production function, $F(\mathbf{x})$, then there exists a cost function, $C(\mathbf{P}, Q)$, such

$$(1) \qquad C(\mathbf{P}, Q) \equiv [\min_{\mathbf{x}} p^T\mathbf{x} : F(\mathbf{x}) \geq Q],$$

where $\mathbf{P}$ is a vector of factor prices; $\mathbf{x}$ is a vector of factor demands; and Q is the amount of output produced. The cost function $C(P, Q)$ as defined by (1) satisfies a number of conditions: nonnegative at all prices and output levels, nondecreasing in output, monotonic increasing in prices, concave in prices, continuous and linear homogenous in prices (see Diewert 1978). This cost function is dual to a production function in the sense that it completely characterizes the economic region of the production function.

For econometric estimation we need to use a specific functional form for $C(\mathbf{P}_L, \mathbf{P}_K, \mathbf{P}_T, \mathbf{P}_M; Q)$ where L, K, T, M refer to labor, capital, land and structures, and intermediate inputs. The cost function specified is an adaptation by Parks of the Generalized Leontief (GL) cost function

$$(2) \qquad C(\mathbf{P}, Q, t) = Q \sum_i \sum_j b_{ij}\, p_i^{\frac{1}{2}}\, p_j^{\frac{1}{2}} + Q^2 \sum_i \alpha_i p_i + Q\, t \sum_i \gamma_i p_i,$$

where p_i is the price of input i ($i = L, K, T, M$), and t stands for time.

Note that continuity and linear homogeneity in prices are the only conditions a priori imposed on the cost function defined by (2). All the other conditions of a cost function, nonnegativity, monotonicity, concavity, and nondecreasing in output will depend on the actual values of the estimated parameters, b_{ij}, α_i, and γ_i. Similarly, symmetry will depend whether $b_{ij} = b_{ji}$ for $i \neq j$. We are interested in determining whether the above conditions hold at least locally for the observed sample points.

Assuming that producers take factor prices as given and using Shephard's Lemma (Diewert 1974) the cost-minimizing input demand functions are defined by

$$(3)\ \mathbf{X}_i = \frac{\partial C}{\partial p_i} = \sum_{j=1} b_{ij} \left(\frac{p_j}{p_i}\right)^{\frac{1}{2}} Q + \alpha_i Q^2 + \gamma_i Q t,$$

where $\mathbf{X}_i$ is the quantity demanded of input i ($i = L, K, T, M$).

Diewert (1971) has shown that the GL cost function corresponds to a fixed coefficient production technology if $b_{ij} = 0$ for all $i \neq j$. Hence, we can test the hypothesis that there is no factor substitution due to price changes by testing whether $b_{ij} = 0$ for all $i \neq j$. Second, it has been shown (see Diewert 1974) that the cost function reflects a constant returns to scale technology if and only if it can be decomposed as

$$(4)\qquad C(\mathbf{P}, Q) = Q\,\tilde{C}(\mathbf{P}),$$

where $\tilde{C}(\mathbf{P})$ is the unit cost function and it is a nonnegative linear homogeneous, nondecreasing, and concave function of p.

Now, from (2) it is apparent that the cost function can be represented as in (4) if and only if $\alpha_i = 0$ for all i. Furthermore, if $\alpha_i \neq 0$ then the cost function represents a nonhomothetic technology. A production function will be homothetic if, and only if, its cost function decomposes as follows (Shephard)

$$(5)\qquad C(\mathbf{P}, Q) = \psi(Q)\,\tilde{C}(\mathbf{P}),$$

where ψ is a continuous, nondecreasing function of Q. It is clear in (2) that if $\alpha_i \neq 0$ for some i, then the cost function cannot be decomposed as in (5). Therefore, if $\alpha_i \neq 0$ for at least one i, then the production function underlying the cost function will not be homothetic.

A change in the input-output ratio can be due to (a) changes in factor prices, (b) changes in the scale of production if the production function does not present constant returns to scale, (c) technological change. In equation (3), it can be easily seen (dividing by Q) that the price and production scale effects are captured by the first and second right-hand side terms. The factor-augmenting technological change effect is captured by the time variable.[2] Therefore, we can test the hypothesis of existence of factor-augmenting technical change by testing whether $\gamma_i \neq 0$ for at least one i. If $\gamma_i = 0$ for all i, then factor augmenting technical change will not exist.

It is assumed that the observed input demands are distributed stochastically about the cost-minimizing input bundles, and thus equation system (3) can be written as

$$(7)\ \mathbf{X}_{in} = \Sigma_j\, b_{ij} \left(\frac{\mathbf{P}_{jn}}{p_{in}}\right)^{\frac{1}{2}} Q_n + \alpha_i Q_n^2 + \gamma_i Q_n t + e_{in},$$

where i is L, K, T, M; n is observation in period n; and e_{in} is the disturbance for input i at observation in period n.

We assume that $E(e_{in}) = 0$, but it is unrealistic to assume that the disturbances are homoscedastic over time. In this respect we follow Parks and assume that the disturbance variance corresponding to input i is proportional to the squared output level, i.e., $V(e_{in}) = Q_n^2\ \sigma_i^2$. This assumption, although arbitrary, does not seem unreasonable, and it is convenient because if we express the factor demand equations in terms of input/output ratios by dividing (7) by Q_n,[3]

$$(8)\ \frac{\mathbf{X}_{in}}{Q_n} = \sum_i b_{ij} \left(\frac{p_{jn}}{p_{in}}\right)^{\frac{1}{2}} + \alpha_i Q_n + \gamma_i t + \mu_{in},$$

$$i = L, K, T, M$$

where $\mu_{in} = \dfrac{e_{in}}{Q_n}$ which has a homoscedastic variance equal to σ_i^2.

To test for symmetry, two variants of (8) are estimated, one without any restrictions imposed and another one imposing the symmetry restrictions, $b_{ij} = b_{ji}$. In the latter model, the disturbance vector $\mu_n = (\mu_{ln}, \mu_{kn}, \mu_{tn}, \mu_{mn})$ will be correlated contemporaneously, which implies that the vector μ_n will have a joint distribution with nonzero covariance. Moreover, preliminary estimates strongly suggested that the disturbances were autocorrelated. Accordingly, the stochastic specification is directed to consider both contemporaneous and intertemporal correlation of the errors. It is assumed that the vector of disturbances μ_n presents first-order autocorrelation and that the 4×4 matrix of autocorrelation coefficients (R) is diagonal, i.e., that μ_{in} is autocorrelated with μ_{in-1} but not with μ_{jn-1} for $i \neq j$. Thus,

$$(9)\qquad \mu_n = \mu_{n-1} R + \nu_n,$$

[2] The trend variable is a poor indicator of technical change mainly because it is unlikely that technical change will be incorporated at a constant annual rate. This problem is quite serious when the objective is to obtain exact measures of technical change. In our case, we aim only to test for the existence of technical change rather than measuring it, and hence the constant rate assumption although not entirely appropriate is less serious.

[3] Preliminary estimates showed that when a set of equations like (7) was estimated the distribution of the error terms indicated heteroscedasticity. This did not happen when (8) was estimated.

where ν_n is assumed to be independently and normally distributed with $E(\nu_n) = 0$ and covariance matrix Σ.

To estimate the parameters of equation system (8) a Full Information Maximum Likelihood (FIML) method developed by Chow and Fair, as adapted by Wales, is used.

The Data

The system of derived-demand equations (8) was estimated using annual data over the period 1946–77. The data used were the prices and quantities indices of the four inputs considered and an output index.

The output variable used was Real Gross Domestic Product of agriculture expressed in 1961 prices. Labor was measured in number of man-hours worked including hired, operator, and family labor. An average annual wage rate index was obtained by dividing the total wage bill paid in agriculture (including an estimated room and board expenditure) by the number of hours worked by hired workers in agriculture. It was assumed that the self-employed workers obtained the same wage rate as the employed workers. The aggregate "intermediate inputs" included fertilizers, seeds, feeds, fuel, and electricity used in farm production. Data on values of the different intermediate input categories were available and an aggregate divisia price index was constructed. An aggregate quantity index of intermediate materials was obtained by dividing total value of intermediate materials into the aggregate price index. A similar procedure was used to aggregate the different categories of capital flows, which included farm machinery, implements, farm vehicles, and animal stocks. It was assumed that the flows of services from the different capital categories were proportional to the respective capital stocks by considering fixed depreciation rates for each type of capital stock. A quantity index for the flow services of land and structures was obtained by using a fixed depreciation rate on the value of the stock of land and structures divided by a rental price of land as calculated by Danielson. General sources for the data were different Statistics Canada publications including the CANSIM data files. Labor data were obtained from publications 21-511, 21-202, and CANSIM. Data on land and buildings, livestock, and machinery were obtained from publications 21-003 and Danielson. Other inputs and gross agricultural output were found in publications 21-511, 61-510, 62-003, and others.

Results

In order to carry out the different tests, likelihood ratio tests were performed. The likelihood ratio test is the ratio of the maximum of the likelihood function under the null hypothesis to the maximum of the likelihood function under the alternative hypothesis. Theil showed that minus twice the logarithm of a likelihood ratio has asymptotically a Chi-square (χ^2) distribution where the number of degrees of freedom is equal to the number of restrictions imposed by the null hypothesis. Table 1 shows the estimated χ^2 values calculated for each of the hypotheses tested and the critical values at 5% and 1% level of significance (LOS) for the corresponding degrees of freedom.

The first row of table 1 shows the corresponding χ^2 for the null hypothesis that the symmetry condition holds, i.e., that $b_{ij} = b_{ji}$ for all $i \neq j$, against the alternative hypothesis of no symmetry, i.e., unrestricted values of the b_{ij} and b_{ji} coefficients. The calculated χ^2 is 6.14, which is lower than the critical values at 1% and even at 5% LOS. Hence, the null

Table 1. Chi-Square Statistics for Various Hypothesis Tests

Note: Asymptotic t-values are in parentheses.

hypothesis of symmetry cannot be rejected at any reasonable level of significance. Accordingly, all further results and tests are obtained using the symmetry restrictions $b_{ij} = b_{ji}$ for all $i \neq j$ imposed. Table 2 shows the FIML estimates of the input/output equations with the symmetry restrictions imposed.[4]

A fixed proportion technology (a Leontief production function) is an extreme situation where the input-output coefficients are independent of input prices or, equivalently, that all elasticities of substitution are zero. This implies in (8) that $b_{ij} = 0$ for all $i \neq j$, which is our null hypothesis against the alternative hypothesis that not all b_{ij} equal 0. The χ^2 values are reported in row 2 of table 1 and show that the calculated χ^2 value is higher than the critical χ^2 values indicating that we can reject the null hypothesis even at 1% LOS. Thus, agricultural production involves a significant degree of factor substitution in response to price changes as reflected by a very large χ^2 value.

The hypothesis of constant returns to scale is also strongly rejected at 5% or 1% LOS. All coefficients corresponding to the output variable (see table 2) present significant asymptotic t-statistics and are all negative. This implies that as the scale of production is expanded, efficiency in the use of factors increases. This is reflected in considerable reductions in the input/output coefficients. If the production function presents constant returns to scale, then all the α_i coefficients would vanish. The high χ^2 values for the test of null hypothesis that $\alpha_i = 0$ for all i allows one to reject that hypothesis. Moreover, the fact that we reject the hypothesis that $\alpha_i = 0$ for all i implies that the underlying production technology is nonhomothetic. Homotheticity implies that the input ratios are independent from output levels. Using (7), we can specify the input ratios

$$(10)\quad \frac{\mathbf{X}_i}{\mathbf{X}_j} = \frac{\sum_j b_{ij}\left(\frac{p_j}{p_i}\right)^{\frac{1}{2}} + \gamma_i t + \alpha_i Q}{\sum_i b_{ij}\left(\frac{p_i}{p_j}\right)^{\frac{1}{2}} + \gamma_j t + \alpha_j Q},\ i \neq j.$$

It is clear that $\frac{\mathbf{X}_i}{\mathbf{X}_j}$ will be independent of the output levels if $\alpha_i = \alpha_j = 0$ for all i, j. Thus, the production function will be globally homothetic if $\alpha_i = \alpha_j = 0$. However, if α_i and α_j satisfy the following condition,

$$(11)\quad \alpha_i \frac{Q^2}{\mathbf{X}_i} = \alpha_j \frac{Q^2}{\mathbf{X}_j}\ i \neq j,$$

then it can be seen easily in (10) that the $\frac{\mathbf{X}_i}{\mathbf{X}_j}$ ratio will not be a function of Q. Obviously, condition (11) can be satisfied only locally for some input-output ratios. Notice that the input-output ratios elasticities with respect to the output scale (ϵ_{iQ}) is $\alpha_i \frac{Q^2}{\mathbf{X}_i}$ and hence condition (11) implies that such elasticities will be similar for the different inputs. We can check whether this condition was met at least approximately for some years in our sample. The fact that the values of ϵ_{iQ} for the different inputs are considerably different in all years would be an indication that homotheticity does not hold (see table 3 where the ϵ_{iQ} are reported for three years).

The χ^2 corresponding to the test of the null hypothesis of no factor augmenting technical progress is presented in the last row of table 1. The χ^2 value is not significant, and hence we cannot reject the null hypothesis. As can be

[4] The unrestricted estimates as well as different indicators regarding the intersample performance of the model are available on request.

seen in table 2, the coefficients of the trend variable are in general nonsignificant with the exception of labor. The nonrejection of the zero technical change hypothesis is quite surprising considering the general conception that technological progress in Canadian agriculture has been important, being labor-saving and capital-using. Thus, the observed decrease in agriculture labor demand and increased capitalization would reflect changes in relative prices and a nonhomothetic production function (which would bend the expansion path towards a higher capital/labor ratio as output is expanded) rather than (biased) technological change. It is interesting to point out that if we impose constant returns to scale, then the hypothesis of zero technical progress is rejected at 5% and even at 1% LOS. In this case technical change appears important, which is consistent with the conventional view and with some previous results obtained in U.S. agriculture where homotheticity was imposed. It is interesting to mention that the hypothesis of zero technical change was not rejected by Lau and Tamura when they used a nonhomothetic production function for Japanese petrochemical industry. As in our case, when they imposed homotheticity, then the technical change variable became significant.

The Own-Price Elasticities and Elasticities of Substitution

In the GL cost function the own-price elasticities, (E_{ii}) can be calculated as follows (Diewert 1974)

$$(12)\quad E_{ii} = -\frac{Q}{2X_i}\sum_{j\neq i} b_{ij}\left(\frac{P_j}{P_i}\right)^{\frac{1}{2}}, \quad i, j = L, K, T, M.$$

The own-price elasticities were calculated at each year's factor prices. Table 3 presents the own-price elasticities of the four inputs evaluated at 1948, 1965, 1977, and at the mean values for the sample. The own-price elasticities for labor, capital, land and structures, and intermediate inputs appear to be inelastic, with values ranging between −0.280 and −0.897. These results are similar to those obtained by Kako for Japan using a translog cost function although the results are not entirely comparable because he disaggregated intermediate inputs into fertilizers and others. The

Table 3. Elasticities of the Input/Output Ratios with Respect to Production Scale (ϵ_{iQ}), Estimated Own-Price Elasticities (E_{ii}), and Partial Elasticities of Substitution (σ_{ij})

	1948	1965	1977	Mean Value
ϵ_{LQ}	−0.363	−1.373	−3.702	−1.392
ϵ_{KQ}	−1.010	−0.920	−1.685	−1.013
ϵ_{TQ}	−0.600	−1.053	−1.710	−1.431
ϵ_{MQ}	−0.960	−0.870	−1.269	−0.959
E_{LL}	−0.280	−0.513	−0.897	−0.517
E_{KK}	−0.455	−0.317	−0.410	−0.347
E_{TT}	−0.464	−0.383	−0.359	−0.422
E_{MM}	−0.455	−0.344	−0.391	−0.410
σ_{LK}	1.428	1.859	2.853	1.779
σ_{LT}	0.054	0.091	0.209	0.113
σ_{LM}	0.623	0.889	1.087	0.875
σ_{KT}	0.290	0.172	0.286	0.234
σ_{KM}	2.531	1.282	1.134	1.555
σ_{TM}	1.285	0.824	0.539	0.991

similarity between own-price elasticities of labor and land is quite remarkable. Kako obtained values ranging from −0.401 to −0.465 for labor and −0.464 to −0.491 for land. The average own-price elasticities for labor obtained by Binswanger (1974b) using U.S. data was −0.911, which is somewhat higher than ours. The estimate for land was −0.336, which is slightly lower than ours.

The Hicks-Allen partial elasticities of substitution (AES) for the Generalized Leontief Cost function can be calculated as follows:

$$(13)\quad \sigma_{ij} = \frac{E_{ij}}{S_i}, \; i, j = L, K, T, M$$

where $\sigma_{ij} = \sigma_{ji}$ is the partial elasticity of substitution between input i and input j, S_i is the cost share of input i, and

$$(14)\quad E_{ij} = \frac{Q}{2X_i} b_{ij}\left(\frac{p_j}{p_i}\right)^{\frac{1}{2}}, \; i \neq j, \; i, j = L, K, T, M.$$

Notice that, in general, $E_{ij} \neq E_{ji}$ but that $\sigma_{ij} = \sigma_{ji}$.

Table 3 presents the partial elasticities of substitution among all input pairs. In general, the elasticities of substitution are all positive but quite small. All input pairs appear to be substitutes, and the highest degree of substitution occurs between labor and farm capital and between capital and intermediate inputs. It is possible that the rather high elasticity of sub-

stitution between labor and capital is related mainly to the inclusion of operator and family labor as part of the labor input component. As the number of operators and the number of farms decrease, there is a trend toward expanding the farm size and degree of mechanization.

On the other hand, the substitution between labor and land and structures is very low and, indeed, it is not significantly different from zero (notice that the coefficient $b_{L,T}$ corresponding to the cross-effect of labor and land is nonsignificantly different from zero). The elasticity of substitution between capital and land and structures also appears quite low although it is significantly different from zero. Thus, labor and land and structures would not be substitutes to each other. Another interesting feature of the elasticities of substitution obtained is that except for σ_{LM} and σ_{TM}, their values are significantly different from one. Thus, the Cobb-Douglas assumption is not supported by our estimates. Similarly, the constant elasticity of substitution (CES) is not supported by our estimates given the rather important variability of the elasticities of substitution estimated for the different input pairs. Hence, it would appear that neither the Cobb-Douglas nor the CES functional form specifications are appropriate for Canadian agricultural production.

Our estimates are quite different from those obtained by Kako for Japan's rice production, although the predominantly positive signs of his coefficients are consistent with ours. Kako obtained a higher elasticity of substitution between land and labor (ranging from 0.760 to 0.816) and a lower one between labor and capital (0.934) than our estimates. The same elasticities may be approximately compared with Binswanger's (1974b) estimates for U.S. agriculture. His estimates were 0.204 for land and labor, 1,215 for land and machinery, and 0.851 for labor and machinery.

It is interesting to determine whether our estimated-demand functions imply a well-behaved cost function satisfying the conditions of a cost function defined by (1). Three properties which may be checked are (*a*) nonnegativity, (*b*) monotonicity, (*c*) concavity in prices. Given that the GL cost function does not necessarily satisfy these properties globally, we checked them at each observation point. However, given that our $b_{ij} > 0$ for all $i \neq j$, our estimated cost function globally satisfies the concavity condition, i.e., the Hessian matrix is negative semidefinite (Diewert 1971). The nonnegativity and the monotonicity properties were satisfied at each observation. Price monotonicity is satisfied if $\frac{\partial C}{\partial p_i} > 0$ for all i, which implies that our fitted demand functions must be positive for all observations. The fitted demand values were calculated for all observations using our FIML estimates. All demand values were found to be positive. In checking for nonnegativity of the cost levels, we followed a similar procedure using the FIML estimates now substituted directly into the cost function. Thus, the estimated cost function satisfies the conditions of a dual cost function; and, hence (given that the symmetry conditions are met), one can conclude that the conditions for economic integrability are satisfied, implying that an aggregate production function for Canadian agriculture exists. Furthermore, this is also an indication that farm producers minimize costs.

Conclusions

A number of important conclusions emerged from the study: (*a*) The derived demand functions satisfy the conditions for economic integrability. This implies that an aggregate cost function and, therefore, an aggregate production function for Canadian agriculture exist. (*b*) Relative factor prices do play an important role in the determination of the demands for the different inputs. Thus, a Leontief type of production function has been rejected. (*c*) The hypothesis of constant returns to scale in Canadian agriculture is rejected. Moreover, the evidence suggests that the production function is nonhomothetic. (*d*) Contrary to the generally accepted opinion, the evidence does not support the existence of factor-augmenting technical progress. The observed reduction in the labor/capital ratio may be due to relative price and output expansion effects rather than to (biased) technological progress. The assumption of a homothetic production function is a crucial assumption when testing for technical progress. When homotheticity is imposed, the output expansion effects on input shares are incorrectly attributed to biased technological change. (*e*) An important quantitative result is that the estimated own-price elasticities of demand are all less than one in absolute value. These results are consistent with the inelastic demands obtained by Kako.

Another interesting finding is that the cross-elasticities of substitution are all positive. In particular, labor is a substitute with all other inputs with the exception of land with which there appears to be no substitution. The highest degree of substitution was found between labor and farm capital inputs.

The Evaluation of the Benefits of Basic Need Policies

Pasquale L. Scandizzo and Odin K. Knudsen

This paper presents a method to quantify social benefits of basic need policies by (*a*) relating their definition to the degree of fulfillment of accepted social standards, and (*b*) recasting the analysis of basic need projects within the general framework of shadow pricing in cost-benefit analysis. An empirical application of this method shows that in poor countries, the attempt at upholding a standard of minimum food consumption for the poor would put substantial premiums on food production over and above world (or domestic supply) prices provided that the increased food supply results in sufficiently higher consumption for the undernourished.

Key words: basic needs, food consumption, shadow pricing, social demand, social standards.

This paper presents a theoretical framework for the analysis of market intervention policies of goods related to the satisfaction of basic human needs. While there has been recent interest in the economic literature for the evaluation of these goals and particularly of nutrition schemes, virtually all studies have attempted to appraise these schemes in terms either of (*a*) specific physical consequences or (*b*) cost effectiveness. For example, Reutlinger and Selowsky utilize a framework where cost effectiveness is defined as the fiscal cost of providing one extra calorie to a target group of consumers. Pinstrup-Andersen and Caicedo compare the consequences of income distribution policies on the calorie consumption of different income groups, while McCarthy uses an input-output framework to extend Reutlinger and Selowsky's method to multipliers' effects.

One of the main reasons cost effectiveness has been considered the natural method of evaluating alternative basic needs policies is that these policies generally are specified in terms of social standards. Given these standards, cost effectiveness assumes that each additional amount of consumption toward the promotion of the accepted requirement carries the same social benefit.

While one can easily sympathize with the simple features of the framework induced by the above assumption, there are several reasons why cost effectiveness appears to be a particularly inadequate method of choice of alternative policy options. First, the target of assuring to all consumers the satisfaction of basic needs is often not one that can be achieved within the limits of government resources or within the realm of time of the policies being examined. Second, it appears reasonable to assume that the consumers whose consumption is further from the targets should receive some priority over the ones which are already close to the requirement levels. Third, while the requirements may be an unequivocal expression of social objectives, private preferences are important to determine the extent to which (*a*) "rich" consumers tend to exceed the targets, and (*b*) "poor" consumers tend to fall below them. Fourth, cost effectiveness only permits a ranking of projects with the same effects on the achievement of the basic target needs. It does not permit comparison of projects with different effects and/or different goods and/or consumers.

The cost-benefit approach suggested in this paper relates to the evaluation of basic needs by specifying a social demand function that takes into account both private preferences and social requirements. Because the number

Pasquale L. Scandizzo and Odin K. Knudsen are, respectively, senior economist and economist with the Agriculture and Rural Development Department of the World Bank, Washington, D.C.

of people whose consumption would fall below the requirement would itself vary with the price of the good in question, both private demand and social demand are shown to be negatively related to price. For a given income distribution, social demand elasticity is shown to be a function of (*a*) the Gini coefficient of income distribution, (*b*) the parameters of the private demand functions of the various income groups, and (*c*) the minimum per capita consumption required by the social standards.

The framework developed is similar to the one suggested by Harberger (1978) in a recent paper, with two important differences. First, Harberger proposes to use the private demand of a higher income class, as the social demand function for the poor. This implies that the social requirement would change with price according to the demand schedule of a predetermined social group whose behavior is used as a norm. Second, because he focuses on per capita rather than aggregate demand, Harberger does not consider the willingness to pay for food distribution at any given price to depend on the number of the undernourished. Thus, in his treatment, the elasticity of social demand and implicitly the social consumers' surplus are only a function of the elasticity of the income group designated as the norm. But in practice, the size of the income group below the poverty line (as designated by the nutritional requirement) is also a function of the price of food. In our analysis, the elasticity of the target group's size with respect to the price of food plays a critical role in determining both social demand elasticity and the social consumer surplus.

The plan of the paper is as follows: the next section presents the theoretical elements of the proposed framework for cost-benefit analysis of basic needs policy, with specific references to food distribution schemes. The third section discusses in more detail the characteristics of the social demand function and its relationship with private and social parameters. The fourth section explores some implications of the theoretical model developed in the first two sections for policy analysis and project evaluation. Then an empirical application to countries is presented, and, finally, some preliminary conclusions are made.

Evaluating Social Benefits of Food Distribution: The Social Demand Function

In determining the demand for basic needs, private parties may not conform to the community's standards for nutrition and health, because they lack information or access to the basic goods or because they do not fully share the standards. Furthermore, the poorest population groups may find themselves unable to achieve the standards because their incomes are too low, prices are too high, or both. In all these cases, the social and the private values placed on a given amount of a "basic need good" tend to differ; the market is then not a reliable means to maximize social benefits.

Figure 1, depicting the demand-price schedule for a typical "poor" consumer, illustrates some of the implications of the fact that private individuals may not behave according to social norms in basic need consumption. In this figure, $C\ C'$ indicates the demand curve of the "poor" consumer, R. The minimum consumption level based on society's standard, and P_m the price that would cause the poor consumer to purchase the minimum level. If actual price P_w exceeds P_m, the quantity consumed will fall short of the minimum level and private demand will be in conflict with social demand.

Consider now the curve $C_w\ C'_w$. This curve is parallel to $C\ C'$ and has the property of causing the consumer to purchase exactly the minimum requirement R at the prevailing price P_w; it is generated by transferring to the consumer the amount of additional income necessary to guarantee, given his preferences, that

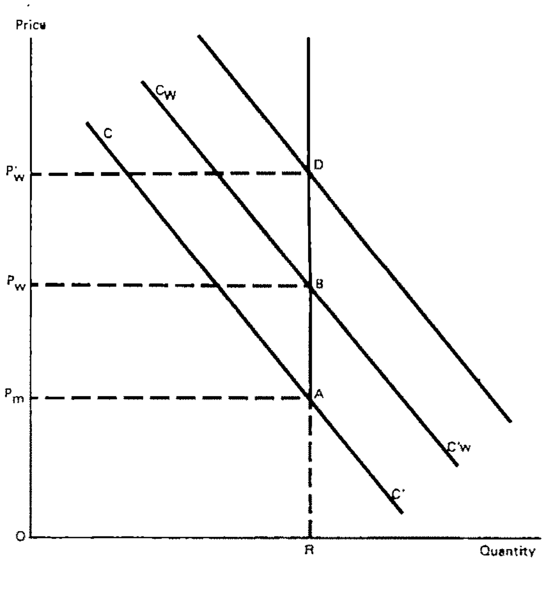

Figure 1. Demand of the poor with fixed social standards

he would buy R. As the figure clearly shows, for any price $P \geq P_m$ we can draw a similar line, but the price-quantity combination will all lie, by construction, on the vertical line ABD corresponding to the minimum requirement. The modified schedule induced by the social standard on private demand can thus be seen as the "kinked" demand curve $C'ABD$.

Figure 2 considers the slightly more complex case where the social standard itself varies with price and could coincide, for example, with the demand curve of a particular income group (Harberger's assumption). In this case the "social" requirement curve is $R\ R'$ and is assumed to be less elastic than private demand $C\ C'$. The socially modified schedule for the individual under examination can now be constructed by a similar income transfer experiment as described above and again will be a "kinked" function, $C'\ AR$ coinciding with private demand for the part of the curve below the intersection with the requirement curve $R\ R'$ and with the latter for the part above the intersection.

The comparison between the demand schedule of an individual consumer and the society's minimum consumption schedule may be useful to shed some light on the size of the per capita difference between actual and required consumption at any given price. Because it fails to incorporate information on the

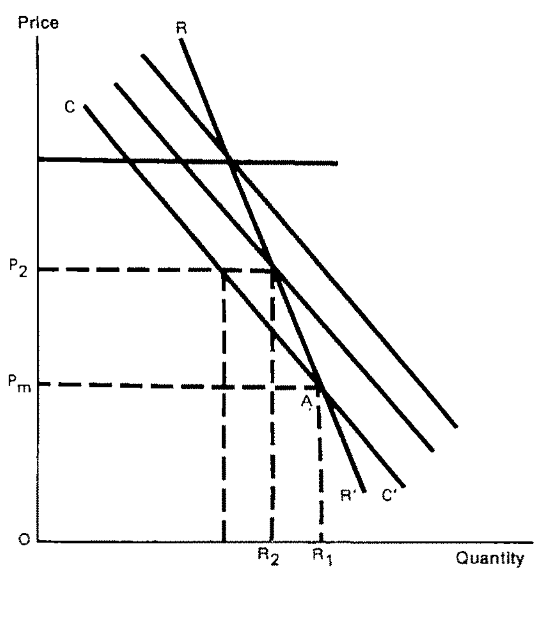

Figure 2. Demand of the poor with variable social standards

other consumers, however, the socially modified individual demand function cannot be used to measure (a) the social gains from increasing consumption up to the standard, and (b) the price that society would be willing to pay for additional units of consumption of people consuming below the requirement.

A more satisfactory way of defining a social demand function is to aggregate the modified individual schedules constructed in figures 1 and 2 and to consider the total demand function for basic needs of a given community. For simplicity, we take the case of food, measured by calorie intake, as an example of basic need good, and we assume that social standards are such that it is generally deemed desirable (a) that any individual consumes at least the amount of food necessary to satisfy some minimum nutritional standard, and (b) that, provided (a) is satisfied, individual preferences are respected. Indicating R as the nutritional standard (which for simplicity we assume invariant with respect to price and across individuals), $N(P)$ as the number of people who would be unable or unwilling to purchase at least an amount of food to achieve the standard at any given prices P, M as the size of the population, and $D(P, Y_i)$ as the amount consumed by the ith individual with income Y_i given prices P, social demand $D_s(P)$ is defined as

$$(1)\quad D_s(P) = R\,N(P) + \sum_{i=N+1}^{M} D_i(P,\ Y_i).$$

This formulation implies that an extra-agent, in addition to the private parties engaged in consumption may enter the market to require the food needed to meet the minimum social standard of the poor. While there is no need to specify who such an agent may be (the government, a charity organization, or the same "rich" consumers), expression (1) specifies the additional amount of food that such an agent, as an expression of a social norm, would transfer to the part of the population whose consumption is below the standard. The demand of this additional social agent will simply equal

$$RN(P) - \sum_{i=1}^{N} D_i(P,\ Y_i).$$

Note that R is not the socially desired minimum consumption level of the poor, but the amount of food that needs to be transferred to obtain a consumption equal to the desired level.

Being a demand schedule, social demand should be a function of prices, but also of incomes. Thus, if the agent seeking to fill the nutritional gap is the government, we may well imagine the requirement R or the tolerated nutritional gap $R - D_i(P, Y_i)$ to depend on government revenue. A similar consideration would apply to a private charity or even to a class of people above the requirement.

Although we could easily introduce into the analysis a basic needs requirement varying with the income of the government or the rich, we believe that it is not essential to the analysis or the results. Within a partial equilibrium framework, therefore, we will simply assume that the requirement is perfectly inelastic with respect to government income. This assumption, of course, is not likely to be respected except within a reasonably narrow range of implied costs and for only the most important basic need goods.

Social Demand and Private Demand

The construction of the social demand function is illustrated in figure 3. This diagram depicts the case of an economy consisting of only two "classes" of consumers: one, the poor, having the demand curve P_1D_1; and the other, the rich, with the demand curve P_2D_2. For the purpose of illustration, we assume that these two classes are equally numerous. While aggregate demand for these two classes is given by the simple horizontal sum of the two demand curves, social demand is obtained by performing the same summation only for the points below P_R, the price under which all consumers choose at least the requirement R. For all prices above P_R and below P_{2R}, the poor would consume below the requirement and social demand would be obtained by summing R (the collective requirement for the first group) with aggregate private demand for the second group. For prices above P_{2R} even the rich would consume below the social requirement, so that society's demand would simply consist of the total requirement (in this case $2R$) for the two groups of consumers.

The above procedure generates the double kinked curve FGD_3, where the two "kinks" are positioned at the prices of entrance of each group in the class of consumers "deprived" (by failing to meet the requirement) of the

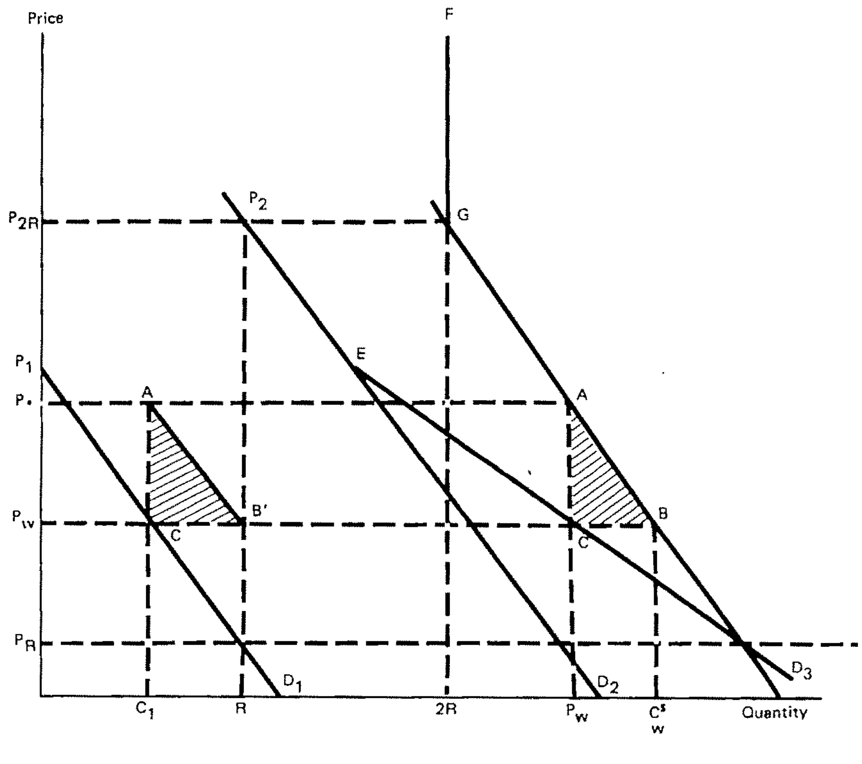

Figure 3. Social demand and private demand for two consumers

basic need good. For many classes of consumers, social demand would have many of these kinks, one for each entrance point and, in the limit for a sufficiently numerous population, it would simply be a curve convex to the origin with a vertical asymptote at the price where all the community would fail to meet the minimum consumption of basic needs and smoothly merging with private demand at sufficiently low prices.

Given a supply price P_w and assuming that the private demand curves are of the Hicks-compensated type (or alternatively accepting the approximation error of considering the uncompensated ones as schedules of willingness to pay), the social price P_* of market consumption C_w is given by the vertical distance between C_w and the social demand curve. The shaded triangle ABC represents the gain to society of a distribution scheme that would raise consumption of the poor up to the requirement level with no expenses on their part. This same triangle can be drawn in correspondence of the poors' demand curve by uniting the point representing social price P_* above the poors' consumption level at price P_w with the intersection of the requirement level with the price line P_w. Clearly, $R - C_1 = C_w^s - C_w$. Because there are only two classes of consumers, the slope of the social demand curve between the two intervention points P_* and P_w is only determined by the constant slope of the demand for one class above the requirement.

Figure 4 shows how the social gain varies with the poverty level of different groups of consumers. For each of the four classes of consumers below the requirement, social demand is obtained with the technique described for figure 3, resulting in welfare triangles whose size decreases as market demand of the corresponding income group approaches the requirement level. Aggregate social demand in the interval between shadow price P_* and supply price P_w is the weighted average of the group specific social demands, given by the downward sloping segments $A'B'$, $A''B'$, $A'''B'$.

Given the social demand as defined *i* (1), the social value or shadow price $P^*(Q)$ of a quantity Q of the commodity is given by the solution of

$$D_s(P_*) = Q, \tag{2}$$

where $P_*(Q)$ can be defined as that price at which the private demands of nonpoor (i.e., those with consumption above the requirement) just equals what is left of Q after meeting the social demand R of the poor (i.e., those with consumption below the requirement). Stated another way, $P_*(Q)$ is the price that would prevail in the market if the poor are supplied R each (out of the total supply Q) and then removed from the market.

Consider now the explicit expression for P_* in the simple case of linear demand functions

(3)

$$D_i = a_i - b_i P + c_i Y_i \qquad i = 1, 2, \ldots, M.$$

Equating social demand to market demand and solving for P_* yields

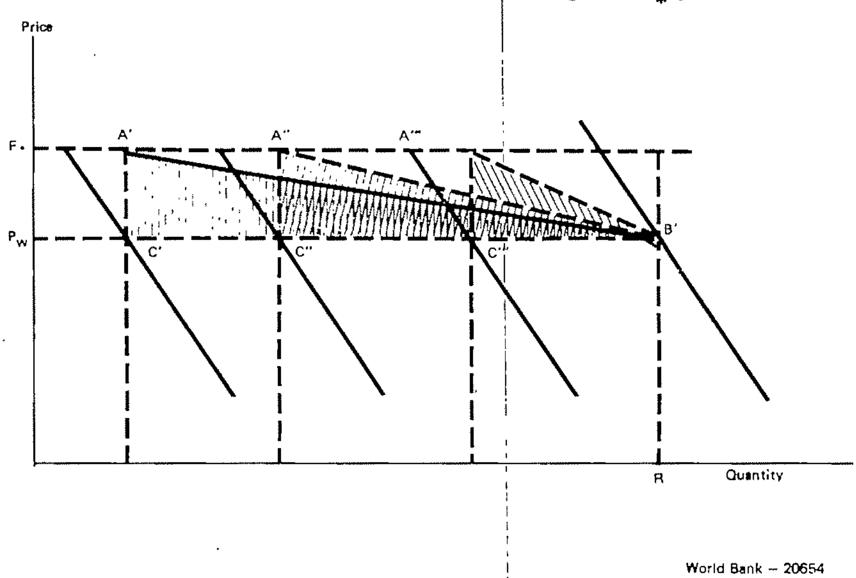

Figure 4. Social gains for different consumers below or at the basic need's requirement

$$(4)\ P_* = P_w + \left[\sum_{i=1}^{N} (R - D_i) \Big/ \sum_{i=N+1}^{M} b_i \right]$$
$$= P_w \left\{ 1 + \left[\sum_{i=1}^{N} (R - D_i) \Big/ \sum_{i=N+1}^{M} |\eta_i| D_i \right] \right\},$$

where $|\eta_i|$ is the price elasticity of demand of the ith consumer group at P_w. Social prices are thus seen to be equal to market prices plus a premium reflecting the social externality of inducing the poor to meet the minimum social requirements. This premium is directly proportional to the nutritional gap of the poor and inversely proportional to the marginal decreases in the consumption of the well nourished in response to a price increase.

The areas of the triangles in figure 4 can be expressed algebraically as follows:

$$(5)\ \Delta_i = \tfrac{1}{2} (P_* - P_w)(R - D_i) \quad i = 1, 2, \ldots, N,$$

where Δ_i indicates the social gain obtained by subsidizing the consumption of the ith undernourished consumer up to the requirement. Substituting (4) into (5) yields

$$(6)\ \Delta_i = 1/2 \left\{ \left[\sum_{j=1}^{N} (R - D_j) \Big/ \sum_{j=N+1}^{M} |\eta_j| D_j \right] \right\} P_w (R - D_i).$$

Therefore, the welfare gain from increasing the consumption of the ith malnourished group up to the requirement is directly proportional to the product of the total nutritional gap and the market value of the group specific gap, and inversely proportional to the weighted sum of the private elasticities of the groups consuming more than the requirement. Note, however, that this method of computing the gain is not "net" of the costs that might be necessary to increase the consumption of the poor. Even if the food transferred is not negotiable, the amount of food needed to cause an equal increase in consumption of the undernourished generally will be larger because the increase in real income will result in increases in consumption of other goods. The poorer the consumer, however, the smaller such a leakage because of the high propensity to consume calories or other basic need goods. Similar provisions also apply to the evaluation of the basic need components of more general transfer schemes and incomes or price subsidies.

More on the Social Demand Function

Consider again the definition in (1) and assume that the country's population is sufficiently numerous to warrant the use of a continuous distribution function $F(Y)$ for per capita income Y. Social demand can then be defined as

$$(7)\ D_s(P) = M\,[RF(Y_P) + \int_{Y_P}^{\infty} D(P,Y)\, d\,F(Y)],$$

where $D(P,Y)$ is the demand for calories of a consumer having income Y at price P, $F(Y)$ is the probability for a consumer to earn an income equal to Y or below it, and $F(Y_P)$ is the probability of earning an income less than or equal to the minimum amount required to purchase R, i.e.,

$$(8)\qquad Y_P \text{ is such that } D(P,Y_P) = R.$$

Adding and subtracting $\int_0^{Y_P} D(P,Y) d\ F(Y)$, i.e., the consumption of the people below Y_p, i.e., from (7), we further obtain

$$(9)\qquad D_s(P) = M \left\{ \int_0^{Y_P} [R - D(P,Y)]\, dF(Y) + \int_0^{\infty} D(P,Y)\, dF(Y) \right\},$$

or (social demand) = (nutritional gap) + (market demand).

Differentiating both sides of (9) with respect to P, we obtain

$$(10)\ (\partial D_s/\partial P) = M \int_{Y_P}^{\infty} (\partial D/\partial P)\, dF(Y),$$

and, in terms of elasticities,

$$(11)\ |\eta_s| = \int_{Y_P}^{\infty} \{[D(P,Y)/D_s]\}\, |\eta(Y)| dF(Y).$$

From expression (11), the elasticity of the social demand function is seen to equal a weighted average of private demand (price) elasticities $[\eta(Y)]$ of consumers above the poverty line, the weights being the ratio between private demand and social demand. Because $\int_{Y_P}^{\infty} [D(P,Y)/D_s]$ is less than or equal to one by definition, social demand elasticity will necessarily be negative and, in absolute value, less than or equal to the elasticity of aggregate private demand.

For a country whose income distribution may be described conveniently by a Pareto

function, social demand can be further specified by focusing on the function $F(Y)$. For any given income Y, the probability of an individual having income higher than Y is given by the expression

$$(12) \qquad F(Y) = [(Y/Y_o)]^{-b},$$

where Y_0 is the minimum income received and b is the Pareto income distribution parameter, which is linked to the Gini coefficient (G) by the expression

$$(13) \qquad b = (1 + G/2G).$$

Assuming for simplicity a constant elasticity private demand for a nutrient,

$$(14) \qquad D = D_o\, Y^{\epsilon}\, P^{-|\eta|},$$

we can find an explicit expression for the minimum income Y_P necessary to purchase the recommended consumption R by equating D to R in (14) and solving for Y_P,

$$(15) \qquad Y_P\,(R,P) = [(R/D_o)]^{1/\epsilon}\, P^{|\eta|/\epsilon}.$$

Substituting this result into (14), we can find the probability of an individual having income lower than Y_P from the expression

$$(16) \quad F(Y_P) = \{1 - [(R/D_o)]^{-b/\epsilon}\, P^{-(|\eta|b/\epsilon)}\, Y_o^{\,b}\}.$$

Taking the partial derivative of $F(Y_P)$ with respect to P, we obtain

$$(17) \; [\partial F(Y_P)/\partial P] = (|\eta|b/\epsilon)\; [1 - F(Y_P)]\; 1/P,$$

and the corresponding elasticity,

$$(18) \quad \eta_P = (|\eta|/\epsilon)(1 + G/2G)\;(1/\pi),$$

where G is the Gini coefficient and π the poverty ratio (i.e., the ratio between the number of people below and above R).

To find a range of plausible values for these parameters, note first that if we neglect the substitution term in the price elasticity of demand, $|\eta|/\epsilon$ in (17) will tend to approximate the budget share (m) for the basic need in question (amalgamated food or calories). Thus, a reasonable interval of variation for this ratio is 0.3 − 0.8. Assuming a Gini coefficient of 0.35, we obtain the values indicated in table 1.

Both expression (18) and table 1 show that the elasticity of the number of malnourished tends to increase rapidly as the poverty ratio π decreases and the ratio $|\eta|/\epsilon$ increases. When food expenditure accounts for a large portion of the budget, in other words, and when the number of calorie-poor individuals is only a small portion of the population, a small increase in price tends to cause a large percentage shift in the size of the deprived group. Furthermore, as expression (18) shows, this elasticity tends to be greater, the smaller is the Gini coefficient; that is, the less concentrated is the income distribution.

The interpretation of η_P is important to understand the meaning of the social demand function. Going back to expression (11), and using (12) and (14), yields

$$(19) \quad |\eta_s| = [D_o P^{-|\eta|}\, |\eta| b/D_s(Y_o)^{-b}] \int_{Y_P}^{\infty} Y^{(\epsilon-b-1)} dY.$$

Assuming $\epsilon < b$ [which is always true for plausible values of G and ϵ because it implies $G < (2\epsilon - 1)^{-1}$] and evaluating the integral in (19), and using the result in (18), we obtain

$$(20) \quad |\eta_s| = \eta_P\{2\epsilon G/[1 - G(2\epsilon - 1)]\}[RF(Y_P)/D_s].$$

In the simple exponential case covered by formulas (12) to (20), we thus have the interesting result that the elasticity of the social demand function is proportional to the elasticity of the probability of being poor, the factor of proportionality being equal to the product of (a) a term reflecting income distribution and

Table 1. Values of η_P for Alternative Values of the Budget Share (m) and the Poverty Ratio (π) (Gini Coefficient = 0.35)

m \ π	1.0	0.67	0.50	0.40	0.33	0.29	0.25
0.3	0.58	0.87	1.16	1.45	1.74	2.03	2.32
0.4	0.77	1.16	1.54	1.93	2.32	2.70	1.79
0.5	0.97	1.45	1.93	2.41	2.90	3.38	3.86
0.6	1.16	1.74	2.32	2.90	3.47	4.05	4.63
0.7	1.35	2.03	2.70	3.38	4.05	4.73	5.40
0.9	1.54	2.32	3.09	3.86	4.63	5.40	6.18

income elasticity, and (b) the ratio between food needs of the poor and total food needs. For any given income distribution and Engel coefficient, therefore, the smaller is η_P, the smaller will be the absolute value of social demand elasticity. In other words, society will be prepared to pay a higher price to subsidize consumption of the poor, (a) the higher is the proportion of the poor over total population, (b) the higher is the proportion of the consumer's budget spent on food, and (c) the more unequal the country's income distribution.

Although only a fixed minimum requirement has been postulated, the definition of social demand therefore implies a social externality plausibly varying with the size of the target group, the importance of food expenditure and income inequality. It is clear that the social gain to raising the consumption of the undernourished depends on the degree by which the consumption of the upper income group lies above the minimum standards. Social demand is thus a function of private tastes and income distribution variables.

Empirical Examples of Social Demand Analysis

In order to estimate the elasticities of social demand and the social gains from meeting the calorie requirement of the undernourished, private demand functions for calorie intake have been estimated for a set of six very poor countries chosen mainly on the basis of the availability of statistics on food consumption by expenditure classes. These countries are Bangladesh, India, Indonesia, Morocco, Pakistan, and Sri Lanka. For each country, the average quantities of the various food items consumed by households in each income group have been converted to calorie intake levels using Food and Agriculture Organization (FAO) calorie conversion tables and the percentages of the population consuming at various calorie intake have been estimated.

In table 2, the fitted regression equations on the household consumption data for the six countries are given. A semilogarithmic function is used as it traced the lower calorie intakes more closely than alternative functional forms and conformed to the Engel curve relationship. In order to introduce the price effect in the demand function, a price elasticity reflecting the income term in the Slutsky decomposition of the price response is introduced by income class by weighting the in-

Table 2. Calorie Regression Equations

Bangladesh	$C = -1779 + 851\ LnY$ (8.0)	$R^2 = 0.97$ $N = 11$
India	$C = -2199 + 1135\ LnY$ (20.1)	$R^2 = 0.99$ $N = 9$
Indonesia	$C = -5659 + 937\ LnY$ (12.9)	$R^2 = 0.98$ $N = 10$
Morocco	$C = -6246 + 1343\ LnY$ (13.0)	$R^2 = 0.85$ $N = 14$
Pakistan	$C = -231 + 603\ LnY$ (13.1)	$R^2 = 0.99$ $N = 10$
Sri Lanka	$C = 479 + 447\ LnY$ (7.6)	$R^2 = 0.99$ $N = 6$

Note: C is the daily calorie intake per capita weighted by the square root of the sample population proportion per class; Y, monthly expenditures weighted by the sample proportions; Ln, indicates natural logarithm of the variable; and N is the number of observations. The regressions are weighted by the square root of the sample proportions to compensate for heteroscedasticity introduced by the varying sample sizes used between expenditure classes.

come-class-specific income elasticity by the ratio of food expenditure to total expenditures.

Because the estimated functions are based on overall consumption data for wide income groupings of large and diverse countries, the following exercise is presented for purposes of illustration more than as a set of empirical findings. To convert the estimates of private demand into estimates of social demand, a social norm for the basic need, in this case food intake or energy (calorie) level, must be established. This social norm, although controversial and to some extent arbitrary, does have some consensus in the case of calories or at least its general range. An FAO/WHO expert committee established calorie intake standards for an average reference man and woman weighing 65 and 55 kilograms for moderate levels of activity at 3,000 and 2,200 calories per day, respectively. Because the average body weights and sex and age distribution of the population are different between countries of the sample, these average requirements range between 2,450 for Morocco, to 2,110 for India.

These estimates assume that each individual has a calorie requirement that corresponds to the average reference man or woman. However, it has been shown that the physiological requirements vary between individuals and over time thereby introducing a stochastic element into the specifications of an aggregate calorie requirement. Following Sukhatme (p. 1383), if we specify for this variation a normal

distribution with a variance σ^2 and a mean μ, the condition of undernutrition may be represented as a calorie intake level below $\mu - 2\sigma$. However, because only scanty evidence exists for estimating σ, the setting of the lower bound for the calorie requirements remains mainly arbitrary. For the purposes of this paper, the FAO/WHO calorie requirement is lowered by 10% or approximately 200 calories to estimate the number of people undernourished and hence the size of the target population. Later, a sensitivity analysis will be conducted on the influence of various norms for calorie intakes on the social gains of a basic needs policy. In table 3, the size of the target population, the level of private demand and social demand are given for the base year of the consumption survey.

Using the estimated calorie demand functions and the expenditure distributions, we have calculated the private and social demand elasticities and social gains from a distribution system that provides sufficient food for the entire population to at least consume the social norm calorie standard. Because of the aggregate nature of the estimates used, these elasticities and social gains results should be construed as approximate and are presented mainly to demonstrate the methodology.

As shown in table 4, the elasticities of social demand are low, varying from nearly 0 for Pakistan to 0.2 for India. The elasticities of the size of the target population are relatively high, ranging from 1.1 to 1.5. This difference in elasticities can be understood by referring to equations (18) and (20). As seen from these equations, the elasticities of the target population are directly proportional to the ratio of the number of people consuming above the calorie requirement to those consuming below the calorie requirement. If the calorie standard were raised, these elasticities would become lower, especially in the case of Pakistan, where the number of people defined as undernourished by the calorie standard is highly sensitive to the standard that is chosen. (Note that the elasticity of social demand is directly proportional to the elasticity of the size of the target population.)

The final columns in table 4 give the ratios on the shadow price to international prices of food distributed to the undernourished and the social gains from a food distribution system that would meet the basic food needs of the population. As shown in this table, this ratio ranges from 1.0 to 3.3 (with the exception of Bangladesh, which presents an extraordinary case and has a ratio that is very high at the accepted calorie social norm), indicating that in project analysis food production should carry a higher value in social benefit cost analysis for countries with widespread undernutrition by possibly a factor of one and one-half to three times, depending on the country, the elasticity of private demand, the extent of undernutrition, and the amount of additional food that will be directly distributed or will "trickle down" to the poor.

In the last columns in table 4, the aggregate social gains and per capita social gains of a food distribution system that meets the needs of the target population are shown. These social gains vary from \$954 million per annum for Bangladesh to \$16 million per annum for Pakistan. Sri Lanka shows no significant portion of the population (as measured by household consumption data) consuming below the calorie requirement. If evaluated on a per capita basis, Bangladesh with significant per capita deficits and large target populations is shown to receive the larger per capita gains from an expanded food distribution system that tends toward fulfilling the calorie requirement of the target groups. As indicated

Table 3. The Size of the Target Population, Private, and Social Demand in the Base Year

Country	Year	Target[a] Population		Private[b] Demand	Social[b] Demand
		(millions)	(% of population)	(millions metric tons)	
Bangladesh	1974	48.5	64	15.3	16.6
India	1973–74	152.8	26	137.0	146.0
Indonesia	1976	58.3	44	27.9	30.1
Morocco	1971	6.1	40	4.0	4.3
Pakistan	1971	37.9	58	13.9	14.2
Sri Lanka	1970	~0	~0	2.9	2.9

[a] The target population is defined as the population with consumption below the calorie requirement.
[b] Calories converted to grain equivalents at 3.5 million calories per metric ton.

Table 4. The Elasticities of Private and Social Demand and the Social Gains from Intervention[a]

Country	Base Year	Elasticity of Private Demand	Elasticity of Social Demand	Elasticity of Target Population	Ratio of Shadow Price to International Price of Food	Social[b] Gains	Social Gains[b] Per Capita	Social Gains per Capita of Population Consuming Below the Calorie Requirement
						(US$mil.)	($/Capita)	($/Capita)
Bangladesh	1974	−0.32	−0.10	1.3	6.30[c]	95.4	12.0	19.6
India	1974	−0.38	−0.18	1.6	1.15	148.1	0.25	0.7
Indonesia	1976	−0.36	−0.16	1.2	1.75	232.4	1.8	4.0
Morocco	1971	−0.35	−0.17	1.1	1.65	28.7	1.9	4.7
Pakistan	1971	−0.17	−0.06	1.5	3.35	116.2	1.8	4.4
Sri Lanka	1970	−0.11	−0.11	0.0	1.0[d]	2.1[d]	0.2[d]	0.3[d]

[a] Calculated for the social norm of 90% of the FAO/WHO calorie requirement for an average reference individual with the exception of the social gains calculations for Sri Lanka which is calculated at 100% of the calorie requirement.
[b] At a price of grain of $277/mton.
[c] Approaching very high levels at the social demand curve as over 60% of the population is consuming below or near the calorie requirement.
[d] Equals the market price of food as nearly none of the population is consuming below 90% of the calorie requirement; the social gain calculations are for achieving 100% of the FAO/WHO calorie standard.

by equation (6), the per capita social gains of any country or expenditure class increases with the degree of the deficit and the difference between the social value of food and the market place. Hence, the social gains are a combined index of the degree of the deficit and the numbers of those with calorie intakes below the requirement.

The elasticity of social demand, the shadow price to international food price ratios, and the per capita social gains all can be considered indicators of absolute poverty, combining measures of the size of the target group with measures of the size of the poverty gap. The framework for the combination is provided by the demand-price correspondence and by a simple assumption on social standards. It should be emphasized, however, that while these standards are largely arbitrary, the measures constructed do not appear to be overly sensitive to the level of the standard set for basic need except at the extremes, where the standard is high and places more than 60% of the population in need or when it is low, indicating that nearly all of the population have achieved the standard. This is important in the case of food as the FAO/WHO calorie requirement is the recommended intake estimated on the basis of the average intake of a healthy, moderately active person of a given population and, as a consequence, has been criticized for being an unrealistically high line to measure undernourishment. As table 5 shows, only as the calorie requirement is lowered (raised) such that nearly all the population is above (below) the social norm does the elasticity of social demand show a noticeable sensitivity. Within these bounds, the shadow price to international food price ratios and the social gains per target member remain at about the same orders of magnitude. Nevertheless, the importance of establishing a consensus on a social norm in the evaluation of a basic needs policy is apparent.

An alternative possibility for reaching such a consensus is to use the criterion that some percentage, for instance, the bottom 30% of the population, are to reach some minimum level of basic needs, e.g., the level at which the top 70% of the population are above. The particular percentile level that is chosen could depend on the degree of current deficits, sizes of the target populations, and the commitment of the society to the alleviation of poverty.

Reference to table 6 would indicate that the

90% *R*	−0.17	—	1.00	0.0 (0%)	0.0

Note: *R* is the FOA/WHO caloric requirement adjusted to account for individual variability.

social norm based on 30% being at least above the basic needs level achieved by 70% of the population would vary from about 90% for Bangladesh and Indonesia, to 100% for India, of the calorie requirement adjusted for individual variability. At these levels of attainment of basic needs, the conversion ratio of food becomes approximately 1.1 to 1.2 for the countries of the sample (excluding Sri Lanka). The social gains per capita of the target population would range between $0.3 and $1.5 per capita depending on the severity of the calorie deficits of these lower 30% of the population. Targeting basic needs policy to attaining a minimum standard for the bottom percentile of the population appears to result in conversion ratios that have some uniformity across these very poor Asian countries and results in greater stability for social gains from establishing an international social norm. This relative standard approach also is likely to represent a more realistic objective in the short term for governments of many countries with extensive undernutrition, than does the attempt to base the evaluation of benefits on an international social standard related to absolute poverty levels.

Some Conclusions

This paper has presented a theoretical framework and some empirical results to estimate the benefits from projects increasing the sup-

Table 6. Elasticity of Social Demand and Social Gains of Meeting the Basic Food Needs of Lower 30th Percentile of Population

Country	Social (Calorie) Norm	Elasticity of Social Demand	Elasticity of Target Population	Ratio of Shadow Price to International Price of Food	Social Gains per Target Population ($/Capita)
Bangladesh	89% *R*	−0.23	2.3	1.15	0.4
India	100% *R*	−0.18	1.6	1.15	0.7
Indonesia	90% *R*	−0.36	1.8	1.20	0.7

ply of necessities to needy groups of individuals. Aside from the characteristics of the measures developed as normative indicators of income distribution, the analysis presented provides a framework and hints of empirical values for the benefits of food distribution and production projects. In all the countries considered, our results suggest that any attempt at upholding a standard of minimum consumption for the poor would put substantial but reasonable premiums on food production over and above world prices provided that the increased food supply results in higher consumption for the undernourished.

Given these results, it is important to underline some of the implications and limitations of our model for project evaluation. First, our definitions of social gains and social demand price closely follow Marshall's definition of consumers' surplus as stated in the *Principles*:

> . . . the price which a person pays for a thing can never exceed, and seldom comes up to that which he would be willing to pay rather than go without it: so that the satisfaction which he gets from its purchase generally exceeds that which he gives up in paying away its price; and he thus derives from the purchase a surplus of satisfaction. The excess of the price which he would be willing to pay rather than go without the thing, over that which he actually does pay, is the economic measure of this surplus satisfaction. It may be called consumers' surplus. (p. 124)

Second, the departure from border price suggested by our estimated conversion factor is subject to the same caveat valid for income distribution weights in project evaluation, that is the political situation must be such that the increase in the standard of living of the poor cannot be obtained via a cheaper tax-transfer mechanism or a better project. Third, the cost for making the additional amount of food available to the undernourished must of course be considered and explicitly in appraising food projects.

A Health Care Systems Model for Nonmetropolitan Areas

James W. Dunn and Gerald A. Doeksen

A health systems model allowing analysis of multiple services including spatial and monetary considerations is presented. Several behaviorally reasonable objective functions reflecting possible goals of the health planner are minimized using mixed integer linear programming. Under the different objective functions, the values of these functions increased little from their optimal value. Sensitivity analysis showed the solution to be quite sensitive to assumptions about migration and treatment practices while birth rates and travel costs have less impact. Use of the model is aided by health planners' use of data at their disposal.

Key words: health system planning, linear programming, mixed integer, rural health.

Health care planning has been required by law since the passage of the Hill-Burton Act in 1946. More recently the National Health Planning and Resource Development Act (PL 93-641) created health systems agencies (HSAs) in each state which are responsible for establishment and implementation of a health system plan and for approval of certain contracts and grants. These agencies do health planning at the state and substate level and advise local decision makers on health planning.

Intelligent health planning requires an understanding of the effects of changes in health service facilities on various groups. The creation of HSAs acknowledges that local health service investments often have impacts beyond the local area. In addition to impacts beyond the local area, investments in one service may affect the usage of other services. Evaluation of these regional impacts on several services is complex, further complicated by different measures of satisfactory health system performance. The complexity of the evaluation process makes it difficult to do without some tool to estimate the effect of an investment. This paper presents such a tool.

The objectives of this paper are: (*a*) to present a model for a regional health care system that includes several services, and which allows comparison of different goals, including those reflecting both spatial and pecuniary motivations; and (*b*) to demonstrate the application of this model in evaluating the difference between conflicting health care goals.

The Model

Researchers, such as Shuman and Wolfe, have stressed the need for a model that incorporates alternative objective functions reflecting the actual goals of the health decision maker. In Oklahoma, the Health Systems Agency specified low cost, availability, and accessibility as major rural health goals (Van Wagner). These objectives may not be attained simultaneously, especially in sparsely populated areas where satisfactory accessibility and low cost may be conflicting goals. Recognizing this, several objective functions have been developed, which incorporate one or more of these goals and which have a behavioral basis. They are (*a*) the sum of all patient's service and transportation costs, (*b*) the total miles of patient travel, (*c*) a quadratic function of patient travel, and (*d*) the sum of the patient's direct costs assuming a 75% coinsurance scheme for the costs of health services.

When these measures are minimized, the first and fourth objective functions address cost from the patient's perspective. The fourth

is an attempt to reflect the importance of third party payments in reducing the marginal costs of health care. Measures (*b*) and (*c*) are related to the accessibility goal. Availability is never addressed directly because all services included in the model are available, although possibly at considerable cost and distance. These objective functions, in addition to being consistent with the goals of the Oklahoma Health Systems Agency, are consistent with certain commonly held beliefs regarding the behavior of health demanders. Because the users determine the usage pattern subject to the actions of the planners, this behavioral basis is necessary for valid modeling.

Several services are considered simultaneously so that the interactions between these services may be included in determining the optimal solution. An interaction of particular importance omitted by separate modeling of physician's services and hospital services is the limitation which physician choice places upon hospital choice and treatment prescriptions (Lubin et al., Feldstein; Smallwood, Sondik, and Offensend). An example of this important interaction in rural areas involves referral of rural residents to specialists in a more populous area. Hospitalization for treatment under such a specialist will be in a hospital convenient to the physician, not to the patient. Also hospitalization in a large, specialized facility will often require a follow-up physician's office visit to the city in which this facility is located.

A spatial equilibrium model using mixed integer linear programming with the alternative objective functions is constructed for solution of each problem. Linear programming is chosen because it has the capacity of handling a large problem for low cost, while still including most of the appropriate features of reality. The mixed integer variation is used solely to evaluate proposed new investments, and does not increase the solution cost prohibitively if a limited number of such investments are considered. This option allows the limitation of investment in new facilities and recruitment of additional physicians to integer units, rather than the continuous units required by ordinary linear programming.

The individual services considered have been modeled by researchers in the past. For example, Duncan and Heady used linear programming to model a nonmetropolitan hospital system for north central Iowa, and Daberkow and King used the branch and bound algorithm to determine the optimal location of ambulance services in northern California. These models have included the availability of other services as constraints but have not allowed for joint optimization which is important, given the joint demand decisions for certain services. Additionally, these models have not made allowances for alternative, and perhaps conflicting, goals.

The purpose of this model is to provide a normative measure of health system effectiveness by finding the optimal system for each objective function. However, it has positive value insofar as its simulation of behavior in the health system (*a*) duplicates actual behavior, or (*b*) provides information regarding potential system behavior not available to health planners from other sources. A model's value as a positive tool is substantiated through validation (Naylor). However, in the area of health system behavior, so little raw information is available that empirical validation is not possible. Where such information is available it is utilized, but, in general, any validation is of the rational variety where the validity of the answers is dependent upon the validity of the assumptions underlying the model. The relationships incorporated in this model that require assumptions regarding actual behavior are believed to be consistent with the existing literature on the relationships in the health system, and any parameters associated with these relationships are believed to be the best available.

The General System

An overview of the operation of the model (see description in Dunn 1977) is shown in figure 1. The system is viewed as having two major sectors, a supply sector and a demand sector. Each sector has spatial differentiation. Within each sector interactions occur which determine the service mixture supply and demand. Using this information the programming model determines the spatial pattern of demand satisfaction.

In the demand sector population characteristics are used to generate service demands. Population statistics are the raw data for the incidence model. These population statistics can be either supplied externally or estimated from prior data using a population prediction model. The incidence model then multiplies the incidence of various ailments for each subset of the population by the size of these popu-

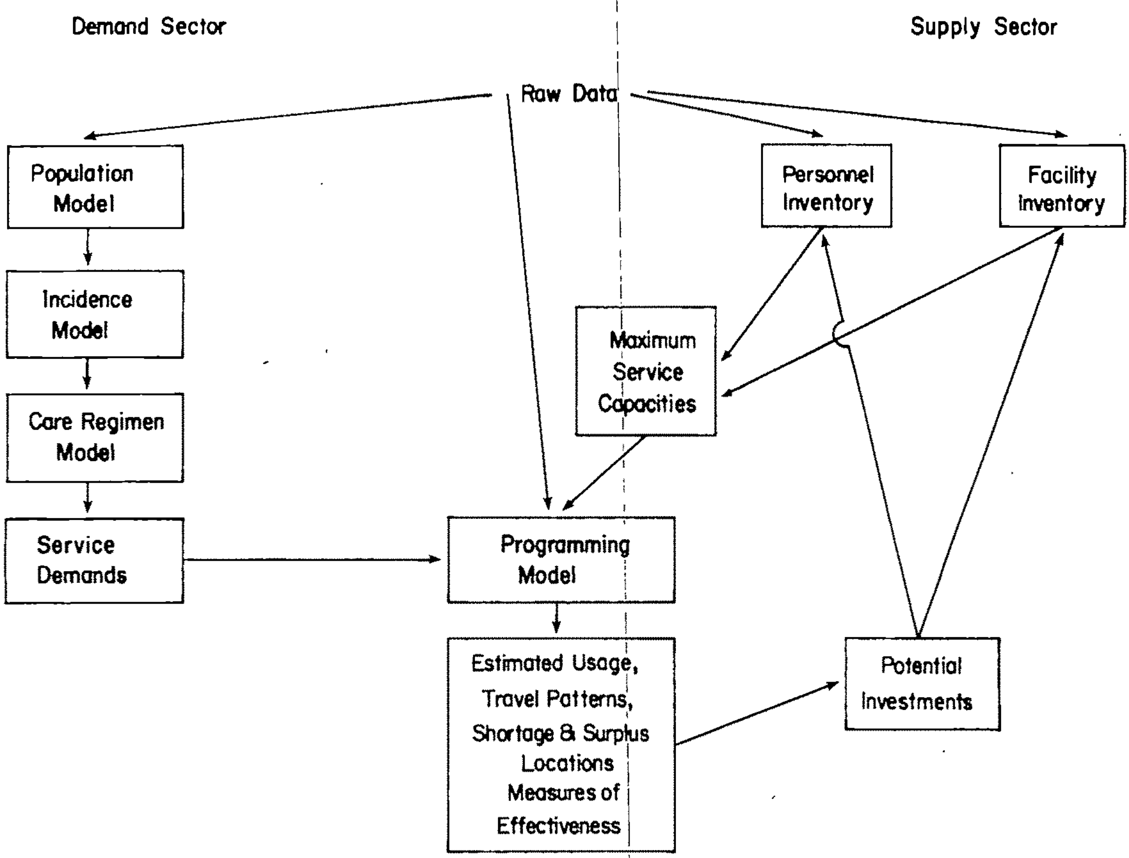

Figure 1. Overview of the solution process

lation subsets, yielding the expected incidence in cases per year. For example, suppose a community has forty men from ages 45–64. This population group has an average incidence of circulatory system problems requiring hospitalization of 40.6 cases per 1,000 population per year. Therefore the forty men in this group in location A would be expected to have 1.624 cases of circulatory system problems per year. The care regimen model associates the incidence of an ailment with a treatment prescription, specified in units of each type of health service required per case of that type by a patient of that type. This yields an expected annual demand for each type of health service by the residents of each location.

The role of price in the level of health care demanded is a source of disagreement between economists and health care providers. Health care providers contend that health care is price independent, while economists contend health care is price responsive. Joseph, in his survey of the empirical research on the demand for health care, found price explained a relatively small amount of the variation in the demand for health care. The data necessitated extension of this small effect to an assumption of no effect. In this model, price is not a determinant of the quantity of health care demanded. A particular ailment calls for a particular care regimen and the demander has no choice in its composition. However, residents choose the suppliers of the services in this regimen, subject to any constraints imposed by their needs for accompanying service, and this decision is based on the criterion implied by the applicable objective function, which may be cost minimization. Therefore, relative price is not a determinant of the quantities of different health services demanded, but it may affect the choice of supplier of particular services.

In the supply sector, the stocks of facilities and personnel in each location are translated into maximum supplies of each service for each supply location. These capacities are constraints for the programming model.

The programming model combines the service demands with the supply availabilities and generates estimated usage of these facilities for each objective function. In addi-

tion to estimated usage, the programming solution also provides travel patterns for patients seeking health care, shortage, and surplus locations, and measures of effectiveness. This information may suggest actions to better balance local supplies and demands, such as potential investments. These proposed investments are processed through the supply sector model to generate adjusted capacities. The programming model is then used to evaluate these proposed investments for each objective function using the various measures of effectiveness. The mixed integer capability allows choice between several remedies to a single problem and simultaneous consideration of several related investments.

Model Application

The model will be demonstrated using a health planning area in northwestern Oklahoma. Five interrelated services are included in the analysis: (*a*) ambulatory care, or physician office visits; (*b*) ambulance service; (*c*) emergency room service; (*d*) primary hospital care days; and (*e*) specialized hospital care days, a combination of secondary and tertiary care days.[1] Were better data available, separation of secondary and tertiary treatment would be preferred. The model is run for each of the four objective functions such that the demand for the five services from the twenty-seven demand locations are satisfied by forty-six supply locations. The supply locations include three locations not in the study area but often used by area residents, Oklahoma City, Amarillo, and Wichita.

Capacity and Interaction

The capacities of health service facilities are important data of the model. Since the demand for health services is irregular, the effective average capacity and the apparent capacity are not the same. Therefore, for hospitals and ambulances a probabilistic method was used to determine average capacity. This involves a queuing theory approach where the maximum average capacity is the mean associated with the maximum allowable probability of a patient requiring service when all available facilities are in use. For hospitals, the probability used was 0.0013, which the Oklahoma Health Planning Commission uses for its estimates of the adequacy of hospital size (Oklahoma Health Planning Commission). That is, the probability that a patient would be turned away cannot exceed 0.0013. For ambulances, an arbitrary probability of 0.0025 was used. Physician capacity was set at 6,500 office visits per year. While some physicians may see more patients, this figure is representative of patient loads for rural physicians (Cordes). Cordes's work is the basis for capacity limitations on other physician's activities, such as hospital visits and emergency room visits. No restriction was imposed on either emergency room visits or on the mix of primary and specialized care days in those hospitals providing both services. Should either of these assumptions be unreasonable, a more restrictive assumption would be necessary.

The interaction between services requires a matrix of amounts of related services accompanying a unit of each service. The coefficients in this matrix are based on information from Cordes; Schonfeld, Heston, and Falk; and from records of several ambulance services in the area in question.

Data Requirements

This model requires data that are available to health planners. The population model uses census data to generate population projections for the period to be modeled, producing estimates of population by cohorts for each demand location. The population cohorts estimated are disjoint subsets of the total population with divisions by sex and age groups, e.g., male 45–64 years. The incidence model uses the mean incidence rate in Oklahoma for the eighteen ailment categories, defined by the National Center for Health Statistics and used in the Blue Cross-Blue Shield record keeping system (May, Doeksen, Green). The care regimen model translates these cases into demand for services using mean hospital stay and percentage of patient days for each ailment requiring primary hospital care or more specialized hospital care based on Oklahoma treatment patterns. The incidence and care regimen models' functions are combined for physician visits, ambulance calls, and emergency room visits because available data for

[1] Primary hospital care involves those basic services of limited complexity available at most hospitals. Secondary care services are of a greater level of complexity and require specialized equipment and personnel which is generally not available in hospitals with fewer than 100 beds. Tertiary care services are of a high complexity and require very high skill levels of personnel and extensive supporting equipment. Tertiary care is usually available only in large hospitals.

these functions are combined (May, Doeksen, Green).

Costs of hospital care are estimated from financial records for a sample of Oklahoma hospitals. The cost per patient day (*COST*) is regressed on the number of services offered (*SER*) and the inverse of the occupancy rate (*OCC*) obtaining:

$$(1)\quad \underset{(11.58)}{COST = 25.72} + \underset{(0.414)}{2.833\ SER} + \underset{(2205)}{11664\ (1/OCC)}, \quad R^2 = 0.726$$

where standard errors are in parentheses.[2] With this equation used to generate the cost of a uniform primary care day, we derive the average cost of a specialized care day by utilizing hospital costs and stays by ailment categories (Dunn, pp. 84–88). Emergency room charges also are estimated using the hospital financial records mentioned above. Physician fees are based on American Medical Association national estimates and vary with community size. The Oklahoma Health Systems Agency considers these estimates to be representative of fees in Oklahoma (Van Wagner). Ambulance charges have two components, a base charge and a mileage charge. Doeksen, Frye, and Green suggest $25 base charge and $1 per mile as reasonable fees for a rural ambulance system (p. 11). A higher base charge is used for the two largest municipal ambulance services. In all cases, confidentiality was a problem, which it would not be for a health planner. Because a health planner is supplied with actual costs and should include these costs in the decision process, actual costs for each supplier could be used rather than estimates.

[2] Cost curves for hospital care have been estimated many times, with wide variations of results between studies; of particular interest is the inconsistent findings about economies of scale. Berki reviews many of these studies and concludes that no answer has been found. Other versions of the above cost equation reflected this.

Results

As specified in the objectives, the model may be used to estimate the impact of many changes in the health care systems, both structural and behavioral, on future system performance. Some of these uses of the model are demonstrated below.

The optimal solution for each of the alternative objective functions was obtained for 1975 to allow comparison of these solutions with the limited data on actual system behavior. The values for each objective function and certain other values when each objective function is minimized are found in table 1. It is apparent in all cases that the percentage changes that occur when different objective functions are used are quite small. This occurs because the major portion of health care activity is conducted locally under all the objective functions. Differences between solutions involve utilization of other than the nearest supplier of a service for one of the objective functions.

The optimal solution when total cost is minimized is presented first and solutions using other objective functions are compared to this. In the minimum total cost solution, some patients traveled beyond the nearest hospital to receive primary hospital care in thirteen of the sixteen counties. The movements corresponded closely with actual patient movements in the system (Oklahoma State Health Planning Agency). Estimated hospital patient days correspond very closely to actual patient days for the region as a whole, a positive reflection on the estimates of the demand model. The estimated usage of individual hospitals varied more, suggesting

Table 1. Comparison of Alternative Objective Functions for 1975

	Minimize Total Cost	Minimize Patient Travel	Minimize Squared Travel	Minimize Variable Cost
Total cost ($)	76,506,000	76,651,000	77,045,000	76,734,000
Patient travel (miles)	85,099,000	83,497,000	85,454,000	83,510,000
Squared travel (miles)²	2,072,684,000	1,994,134,000	1,934,521,000	1,994,461,000
Variable cost ($)	28,700,000	28,581,000	28,875,000	28,578,000
Net subsidy for hospitals ($)	4,449,000	4,408,000	4,408,000	4,408,000
Ambulance emergency miles	123,000	125,000	125,000	123,000
Ambulance transfer miles	61,000	50,000	50,000	50,000
Nurses required in area	593	608	608	608
Physician miles	683,000	650,000	650,000	664,000

an inadequacy of the cost estimates or of the decision criterion or both. The first deficiency could be remedied by the use of actual data, the second may potentially be improved by other objective functions. Because the alternative functions provided mixed results, aggressive use of the model as a predictive tool would require careful consideration of the objective function appropriate for one's purposes.

While data on actual physician patient loads are not available for the area, estimates duplicated the findings of Cordes: there was a heavier physician patient load for rural practices than for the nation as a whole. The interaction between services seemed to work quite well, especially the constraint placed on hospital usage by physician availability. While this comparison is rather subjective, in several hospitals where physician availability does restrict hospital usage the model reflected such a restriction. The estimated hospital capacity levels included in the model were lower than actual usage in several instances indicating the actual probability of excess patient demand is higher than the model's assumed probability. For planning, use of effective capacities higher than the usage levels planners consider prudent is illogical, except for comparisons.

As table 1 illustrates, the different objective functions have only minor impacts on the optimal value allowed in the program. Differences occur in usage of certain key hospitals for which market shares are quite sensitive to changes in the way travel is viewed. These hospitals all supply both primary and specialized care, and serve areas with several alternatives for specialized care. In such cases, many factors may determine the choice of hospitals and alternative objective functions including considerations other than travel and cost might be especially appropriate.

Cost minimization explains actual behavior better than other objective functions. This may be because it includes the major characteristics of the other objective functions which are more narrow in perspective. However, these other functions have important normative value, and they reflect possible measures of effectiveness for health planners.

Effect of Changes in the Assumptions

The dependence of linear programming upon its underlying assumptions causes any error in these assumptions to be of special interest. Five changes in assumptions are investigated, two in the method of population prediction, two in demand determination, and one in the cost of patient travel. These are all compared to the minimum cost solution for 1985.

In recent years, major overprediction of the nation's population by demographers occurred because the assumed birth rates were too high (Irwin). Additionally, rural population projections have been off because of inaccurate estimation of off-farm migration. Recognizing the uncertainty associated with these two elements, a test of their importance in health planning is desirable.

As hospital costs increase relative to prices in general, the role of home convalescense may increase. This would result in a reduced stay in the hospital for the same ailment. Improved medical knowledge may increase the speed of recovery causing the same effect. Hence, a reduction in length of hospital stays seems likely and its effect is also investigated.

Increased specialization in health care has dramatically affected the practice of medicine in recent years. Additionally, technical advances have made available a variety of expensive and specialized equipment for those who can afford it. Continuation of this trend toward increased specialization seems likely and the effect of increased specialization is accordingly considered. The possibility of petroleum prices increasing faster than the general price level is discussed frequently. Because petroleum cost is a major cost of travel, a relative increase in travel costs is also considered.

These alternative assumptions were chosen because they either represent a potentially large source of error, in the case of migration assumptions and birth rate changes in population prediction, or because they represent likely changes in the system in future years. The estimated total hospital patient days for the hospitals in the study area under the varying assumptions are shown in table 2.

The effect of changes in population projections stems from changes in the assumptions concerning net-migration and birth rates. Rather than estimating net-migration based on past movements, no net-migration was assumed. This, of course, has different effects for different communities, while an assumption of lower birth rates reduces population in each location by approximately the same amount.

These two changes have quite different effects on the demand for services. In the model

the assumption of no net-migration affected each cohort proportionately, thereby affecting the demand for each service by the same amount, an aggregate increase of 3.9% over the base amounts. The assumption of lower birth rates, on the other hand, affects the size of only the youngest cohort, having no effect on older cohorts. This means that services utilized most heavily by older persons remain relatively unaffected; e.g., ambulance calls fall by only 1.1% while population falls by 6.5%. Emergency room visits, for which only overall usage rates are available, fall by 6.5%. Physician visits, which have relatively equal rates for all population cohorts, fall by 5.6%, while primary and specialized care hospital bed days fall by 1.7% and 1.6%, respectively, reflecting the higher hospitalization rates for older people.

The effect of the assumption of no net-migration on aggregate hospital use in the study area was an increase in patient days from 320,879 to 333,722. Individual hospitals were affected very differently depending upon what the estimated migration for that county had been in the base model. The assumption of lower birth rates, while affecting different hospitals in different ways, had a much more uniform effect, generally a small decrease in usage. In either case the effects on particular facilities can vary, and these changes can have major effects on the optimal size for a new facility. Because hospital construction costs are approximately $65,000 per bed (Hanson, Doeksen, Green) overbuilding by several beds can be a substantial burden on a community.

Increased specialization is accomplished by increasing the specialized care portion of hospital days by 10% for each ailment, the residual being primary care days. This results in an average decrease in primary care days of 3%. While total patient days for hospitals in the study area remain virtually unchanged, the constraints of capacity for some hospitals and the complementarity between physician visits and hospitalization cause the changes to be spread unevenly throughout the system. Also, hospitals supplying both primary and specialized care days are affected differently than other hospitals. These changes are important enough to make consideration of alternative scenarios essential in estimating usage of facilities for health planning purposes.

All hospitals are adversely affected by a 10% stay reduction. Hospitals which were particularly hard hit were those which receive some spillover from nearby hospitals which were operating at full capacity. Stay reduction in these cases decreased patient days by substantially more than 10%.

The final change considered is the effect of increasing travel cost by 100%. Its effect on system behavior is minimal. Total cost increases from $74,321,000 to $74,511,000, a 0.26% rise, and the changes in the solution reduce mileage by only 32,000 miles. The changes are small because local facilities generally have a cost advantage meaning travel is already at a minimum, except where constraints prevent it.

Projecting Future Health Needs

An important task of health planners is estimating future usage of services to better evaluate the need for construction and staffing of proposed facilities. This is a continuing process because existing facilities need replacement and present personnel retire or leave. A major use of the model is projection of the use of the system over some future period. The larger study (Dunn) projected fifteen years of future usage evaluating for this period several investments to alleviate shortages, and several strategies for replacing retiring physicians. Because each instance is unique, specific results are not presented here. Projection of fu-

Table 2. Projected 1985 Utilization of Health Facilities by People of the Study Area under Different Assumptions

	Service Type				
Assumption	Primary Care Days	Specialized Care Days	Ambulance Calls	Physician Visits	Emergency Room Visits
Base model	261,720	73,733	6,695	818,171	35,939
No net migration	271,927	76,609	6,959	850,080	37,341
Lower birth rates	257,474	72,701	6,621	772,353	33,603
Increased specialization	254,347	81,106	6,695	818,171	35,939
Reduced stay	235,548	66,360	6,695	818,171	35,939

with identification of the set of noninferior solutions in decision ($\mathbf{X}^*$) and objective [$z(\mathbf{x}^*)$] space, the shadow prices suggest trade-offs among objectives for each noninferior solution. The array of noninferior decisions with corresponding values of objectives and trade-offs can then be set before the decision maker. Moreover, if $k < 4$, the solutions and trade-offs can be depicted graphically, thereby facilitating the evaluation of alternatives by the decision maker.

Because GP terminates in one decision vector rather than exploring the noninferior set, the results of this procedure do not quantify and make the trade-offs explicit. Thus, the decision maker in a GP paradigm is asked *ex ante* for values of targets (T_i), and perhaps weights (w_i), without knowledge of the range of feasible (let alone noninferior) solutions and is returned a single decision vector (or several if sensitivity analysis is undergone), with insufficient information on alternatives and trade-offs among objectives. Moreover, as Morse (1977, p. 23) suggests, "The duals in GP lose much of their interpretability." His development is quite detailed, but is based on the fact that while in linear programming the objective function coefficients are related to columns (not rows) of the constraint matrix and are independent, in GP the actual decision variables (**x**) have zero objective function coefficients and "the audit trail on the information inherent in the problem's coefficients leads primarily through the RHS of the policy constraints into the objective function" (p. 15). Further, because the policy constraints (14) contain both slack and surplus variables, the optimal basis is degenerate. And the system is driven by a set of weights (w_i) which are not independent.[3]

Quantity of Information

The information supplied is clearly related to the previous criterion. The explicit quantification of trade-offs is possible only if the problem and solution procedure are formulated in a realistic manner which supplies sufficient information for this purpose. The maximum amount of information which can be supplied by the technique is the set of noninferior solutions and the set of all trade-offs among objectives. The weighting and constraint methods provide this maximum quantity of information.

Optimization theory generally involves assessing the relative value of additional increments of the various objectives, given levels of all objectives, rather than assessing their absolute values. Moreover, at any given level of all objectives, it is generally simpler for DMs to evaluate the relative value of trade-offs (marginal increases and decreases) between any pair of objectives than to evaluate their absolute values. Thus, the generating techniques provide sufficient information such that DMs need only assess whether an additional amount of one objective is worth more or less than that which must be sacrificed of another, given the current levels of each. The desire of the DMs, then, would be to find a solution such that they are indifferent between the additional unit of all objectives and their corresponding opportunity costs, given levels of all objectives.

Other techniques, including GP, provide a weaker information set for several reasons. First, because such techniques are designed to reduce the computational requirements and expense by eliciting preference information prior to the problem solution and hence eliminating the search for the complete noninferior set,[4] these approaches provide less information. Second, the quality of the information which is made available by such approaches (which involve obtaining information from the decision makers on subjects about which it is unreasonable to believe they are well informed) is likely to be diminished. This second reason will be expanded upon below. It is sufficient here simply to suggest that more (the maximum) information is supplied by the generating techniques than by goal programming.

Validity of DM-Analyst Interaction

The four criteria used here are fairly awkward and subjective, but probably more useful than some more quantifiable index one might contrive in order to make "less subjective" comparisons. This fourth criterion is defined even

[3] This is true if the weights are chosen as convex combinations (e.g., w_i sum to one). Even otherwise, changing any weight changes all relative relationships among the w_i.

[4] The remaining sets of techniques elicit information from DMs during the solution procedure, but prior to the final solution results. Examples include the Stem method developed by Benayoun et al. and the approach suggested by Candler and Boehlje. An evaluation of several such interactive approaches is provided by Wallenius. In the interest of brevity, these "black box" approaches are not reviewed and compared here.

offs, amount of information supplied, and validity of DM-analyst interaction. It is important to be clear that these comparisons are of generating techniques with GP as it was designed to be, and generally is, used. To be sure, Kornbluth, Brill, and others show how GP could also be used as a generating technique rather than requiring a prior complete specification of G. Indeed, as shown in the appendix the GP formulation (11) through (15) can be made similar to the weighting method (4)–(6) for this purpose. But the present comparison is of methods which require only a partial specification of G with one which, as designed and generally used, requires a complete specification of G. These comparisons suggest that neither approach is superior by all four criteria, so that choice of method will depend on the situation and the analyst's evaluation of the importance of these criteria.

Computational Expense

Because planners typically operate in a world of constrained budgets, computational expense is an important attribute of an adopted decision technique. Candidate measures of computational expense might include dollar costs, computer time, and number of required solutions of a scalarized version of the original problem. Our comparison uses the latter, because the first two are unavoidably problem- and computer-specific.

For the weighting and constraint methods, the number of solutions needed to identify or approximate the noninferior set ($\mathbf{X}^*$) increases with the number of objectives and the chosen level of approximation. Indeed, if N is the number of values of each w_i of (4) used in the weighted method or b_i of (9) in the constraint method, then the number of solutions needed (R) will be an exponential function of the number of objectives (k), namely,

$$R = N^{k-1}. \tag{16}$$

Thus, if one were to apply the constraint method and vary each b_i over six intervals ($N = 6$) for a four objective ($k = 4$) model, then $R = 6^3 = 216$ solutions of the scalarized version would be required. The addition of one more objective would raise the number of required solutions to 1,296.

Goal programming is clearly computationally efficient relative to the generating techniques. Technically, only a single solution of this scalar version of the multiple objective problem needs to be found. However, if solution sensitivity to target levels (T_i) of the k objectives is desired, additional solutions are needed (again, we refer to efforts short of attempting to span the entire noninferior solution space). And if alternate weights (w_i) are to be examined, even more problems need to be solved. Moreover, extensive sensitivity analysis is often required to insure that the GP solutions are noninferior.[2]

In summary, the computational burden of generating techniques is high relative to GP. This is because these methods are based on the incomplete orderings associated with the k objectives, such that alternatives can be dismissed only on the basis of noninferiority. For this reason, the usefulness of techniques such as the weighting and constraint methods is highest for cases in which $k \leq 4$, and diminishes rapidly with increasing numbers of objectives. In addition to the escalation of computer expense and reduced tractability, the appeal of these methods, from the standpoint of offering the decision maker the right kind of information upon which to make choices, disintegrates with the "information overload" brought about by the generating technique solutions with high-dimensioned objective space. Clearly, with $k \geq 4$, the analyst no longer can present the DM with a graphical depiction of $z(\mathbf{x}^*)$. This latter point relates to the other criteria for comparing methods.

Quantification of Trade-Offs

It probably would not be difficult to reach a consensus that for decisions with multiple conflicting objectives, economic analysts can best serve the decision-making process by making clear the trade-offs involved in the alternative choices for the given situation. Certainly, this is a central premise of the work by Marglin (1967), Maass, and many others. Thus, to best serve the public (political) decision-making process, the multiple objective technique should make these trade-offs clear and hence foster (force) the explicit consideration of these opportunity costs.

By this criterion, the weighting and constraint methods are ideally suited to public multiple objective decision making. Along

[2] Cohon and Marks (1975) illustrate this point graphically. It is easily seen that a DM articulating preferences (w_i, T_i) in the absence of knowledge of the noninferior solution space may select levels of T_i, for $w_i > 0$, all of which are feasible and at least one of which can be improved. The GP solution would achieve these levels of T_i and would be inferior.

mathematical programming software packages, with the initial w_i arbitrarily set.

The constraint method is essentially the dual of the weighting approach. It also involves finding noninferior solutions by solving a scalar version of the original multiple objective problem. Because it is relative values of weights that are important, the approach involves selecting the jth objective to maximize subject to the problem constraints plus lower bound constraints on the remaining k-1 objectives. Thus, the original problem becomes

$$(7) \qquad \max z_j(\mathbf{x}),$$

subject to

$$(8) \qquad \mathbf{x} \in \mathbf{X},$$

$$(9) \qquad z_i(\mathbf{x}) \geq b_i, \qquad i \neq j,$$

$$(10) \qquad \mathbf{x} \geq 0,$$

where b_i are the lower bounds on the k-1 objectives. The initial lower bounds can be set by solving the k problems of maximizing (7) subject to (8) and (10), where each j ($j = 1, \ldots, k$) is used in (7) in the k separate solutions, substituting the values of $\mathbf{x}$ for each of the k optimal solutions into $z_i(\mathbf{x})$, and selecting for each $z_i(\mathbf{x})$ lowest of the k values as b_i. The noninferior solution set is then found by solving (7) through (10) with parametric variation of b_i and substitution of each $z_i(\mathbf{x})$, $i \neq j$, into equation (7).

While the weighting and the constraint methods appear similar, the constraint method is generally preferred because it will always solve for the noninferior solution space. By contrast, the weighting method will span the noninferior solution space only under the condition that the objective space is strictly convex. This is demonstrated by Cohon and Marks (1973), who argue that the constraint method also is favored for operational considerations—viz., that parameterization of right-hand sides is more straightforward than parametrically varying weighted coefficients in the objective function.

Among the applications of these techniques are the works of Cohon and Marks (1973), who evaluated the trade-off between net national income and equity of regional income distribution for a developing country; Miller and Byers, who examined the trade-off between environmental quality and income for an agricultural area; and Miller and Erickson. Perlack and Willis and Sinha, Perlack and Willis apply the technique to generate noninferior solutions for a sludge disposal problem for a major metropolitan area. Economic efficiency, environmental impacts, and risk were considered explicitly as objectives in this work. These applications include linear and nonlinear objective functionals and constraints.

Goal Programming

Goal programming is one of the popular techniques, which requires a more complete articulation of preferences prior to solution. Developed by Charnes and Cooper in 1961, it is based upon minimization of the sum of weighted absolute deviations of objectives $[z_i(\mathbf{x})]$ from targets (T_i). Thus, the GP formulation of the initial multiple objective problem is

$$(11) \qquad \min \sum_{i=1}^{k} w_i(d_i + e_i),$$

subject to

$$(12) \qquad \mathbf{x} \in \mathbf{X},$$

$$(13) \qquad \mathbf{x} \geq 0,$$

$$(14) \quad z_i(\mathbf{x}) - d_i + e_i = T_i, i = 1, \ldots, k, \text{ and}$$

$$(15) \qquad d_i, e_i \geq 0,$$

where d_i and e_i are the positive and negative differences of the ith objective from its target, respectively, and w_i is the weight or priority attached to the ith goal. The w_i can also be split into two components—one for positive differences (d_i) and one for negative differences (e_i). Neely, North, and Fortson provide an example.

In addition to the Neely, North, and Fortson work mentioned earlier, examples of GP applications include: a similar application by North, Neely, and Carlton (1977); Charnes, Cooper, and Ferguson, who apply the technique to executive compensation levels; Harald et al., who use GP to evaluate managerial standards for a program of marine environmental protection; Sfeir-Younis and Bromley, who evaluate public investments in LDCs; and Lee, who reports applications in the areas of finance, marketing, school bussing, accounting, and a number of others. The survey of GP by Kornbluth also provides useful background in this area.

Comparison of Methods

Recall that the criteria for evaluation are computational expense, quantification of trade-

plicit quantification of tradeoffs, quantity of information supplied, and validity of DM-analyst interaction.

The next section describes the vector optimization concept and a portion of the available multiple objective decision-making techniques, featuring the generating class and goal programming. These descriptions can be supplemented by reference to the excellent survey by Cohon and Marks (1975) and to Bishop et al., among others. The subsequent section contrasts the generating and GP techniques according to the four criteria indicated above. A final section summarizes the points made and offers some parting observations.

Vector Optimization

The problem of multiple objective decision making generally can be described as

$$(1) \quad \max z(\mathbf{x}) = G[z_1(\mathbf{x}), z_2(\mathbf{x}), \ldots, z_k(\mathbf{x})],$$

subject to

$$(2) \quad \mathbf{x} \in \mathbf{X}, \text{ and}$$

$$(3) \quad \mathbf{x} \geq 0,$$

where $z(\mathbf{x})$ is the k-dimensional objective function (there are k objectives); $\mathbf{x}$ is an n-dimensional vector of decision variables; (2) is the set of m constraints for the problem; and (3) is the set of nonnegativity conditions. Equations (2) and (3) define the feasible region in n-dimensional Euclidean space. Each feasible solution to the problem implies a value for each objective $[z_i(\mathbf{x}), i = 1, \ldots, k]$. The k-dimensional objective function (1) maps the feasible region in decision space ($\mathbf{X}$) onto the feasible region in objective space $z(\mathbf{X})$, which is defined in k-dimensional Euclidean space.

With the operator G completely unspecified, it would be impossible to order the objectives, and the vector (1) cannot be optimized. Without information about preferences with which to combine objectives, the objectives are incommensurable and solutions cannot be compared.

However, even in the absence of complete value judgments about the k objectives, a portion of the feasible solutions can be dismissed on the basis of a partial ordering. With the assumption that more of each objective is preferred to less, only the noninferior solutions are relevant. A noninferior solution is a feasible solution to the problem, $\mathbf{x} \in \mathbf{X}$, such that no other feasible solution, $\bar{\mathbf{x}} \in \mathbf{X}$, exists for which $z_p(\bar{\mathbf{x}}) > z_p(\mathbf{x})$ for some $p = 1, 2, \ldots, k$, and $z_i(\bar{\mathbf{x}}) \geq z_i(\mathbf{x})$ for all $i \neq p$. Noninferior solutions can be defined in decision space ($\mathbf{X}^*$) as well as in objective space $[z(\mathbf{x}^*)]$, because each noninferior solution $\mathbf{x} \in \mathbf{X}^*$ implies a value for each of the k objectives $z(\mathbf{x})$. The techniques described below are methods of generating or solving for the set of noninferior solutions to the problems (1)–(3), where the operator G is specified such as a partial ordering. Noninferior solutions are preferred to inferior ones, and any further ordering of noninferior solutions is done by the DM after receiving the model results.

Generating Techniques

The primary approaches included in the class of generating techniques derive directly from the Kuhn-Tucker conditions for noninferior solutions (Cohon and Marks 1975, Brill, Bishop et al., Roy, and Wallenius). These techniques were developed with the objective of identifying $\mathbf{X}^*$ and $z(\mathbf{X}^*)$. Without preferences (value judgments), these techniques provide all the information which can be derived from a multiple objective model.

The weighting and constraint methods[1] are the most common of the generating techniques, both following from Kuhn and Tucker. The weighting method involves solving for noninferior solutions by converting the original problem defined by (1)–(3) to a scalar optimization problem, in which the objective function becomes a weighted sum of the arguments of (1). That is,

$$(4) \quad \max \sum_{i=1}^{k} w_i \, z_i(\mathbf{x}),$$

subject to

$$(5) \quad \mathbf{x} \in \mathbf{X},$$

$$(6) \quad \mathbf{x} \geq 0,$$

where $w_i \geq 0$ for all i and strictly positive for at least one. Thus $\mathbf{X}^*$ and $z(\mathbf{X}^*)$ can be generated by parametric variation of w_i with existing

[1] The rudiments of the weighting and constraint methods are found in the works of McKean, Marglin (1962), Eckstein, and Freeman. Their intent was not to generate the entire noninferior set, but rather to identify an optimal set of weights and then proceed directly to the social optimum. Candler and Boehlje do likewise in an interactive mode.

A Comparison of Generating Techniques and Goal Programming for Public Investment, Multiple Objective Decision Making

C. E. Willis and R. D. Perlack

The move toward public decision making based on multiple objective analysis has occurred largely during the past decade. During this brief interval dozens of techniques have been advanced for this purpose. The class of (generating) techniques which do not require prior articulation of preferences and which provide alternative solutions rather than a single optimum is characterized and compared to goal programming. Goal programming, as generally employed, seeks a single optimum solution given an articulated set of targets and priorities on the relevant objectives. Four criteria were used in this comparison and neither approach was found to be unambiguously superior.

Key words: generating techniques, goal programming, multiple objective decision making.

The ongoing transformation in many public policy areas from decision making based upon traditional planning models featuring a single objective to multiple objective analysis has promoted a field of mathematical programming called vector optimization. This field is not new, having been created in 1951 by Koopmans and by Kuhn and Tucker. It has been only in the past decade, and particularly during the latter portion of it, that serious effort has been given to developing solution techniques for these types of problems. During this relatively brief interval, more than two dozen different techniques for solving multiple objective programming problems have been advanced. Many of these are confined to the generation of the set of noninferior solutions to the problem, and do not require an articulation of preferences among goals by the decision maker (DM). The remaining techniques do require a prior, or a sequential, articulation of preferences, with the result being a single optimum solution rather than a set of noninferior solutions.

With some notable exceptions, agricultural economists have lagged a bit behind other operations researchers and management scientists in adopting these techniques. Most exceptions have involved the use of goal programming (GP) or lexicographic programming (a form of GP with preemptive weights), which require an articulation of preferences. Neely, North, and Fortson provide a recent illustration of the use of GP for multiple objective decision making for public water resources projects.

The present purpose is to characterize the class of multiple objective (generating) techniques which do not require a prior articulation of preferences and which provide alternative solutions rather than a single optimum decision, to characterize the GP approach as one technique within the class of approaches which provide an optimum solution given an articulated set of targets and priorities on the relevant objectives, and to evaluate the strengths and weaknesses of these two approaches. Ultimately, the choice among these available approaches for any given problem itself involves comparison relative to multiple objectives, e.g., computational expense, ex-

ture use is where the mixed integer capabilities become important, because investment is a major consideration in future planning.

This paper describes a health systems model which allows analysis of multiple services and includes spatial and monetary considerations. The model and its validation are discussed and empirical results are presented for a health systems area in northwestern Oklahoma. Several objective functions were minimized, each behaviorally reasonable while reflecting possible goals of the health planning decision makers, and the differences resulting from these alternative objective functions are examined.

Also several assumptions regarding future changes were tested and the impact of these changes were examined. Where information for empirical validation is available it is utilized, but in general validation is of the rational variety. The empirical validation conducted showed the model to be strongest in the very rural areas and weakest within the commuting areas of cities. The solution was quite sensitive to changes in migration and treatment practices and quite insensitive to changes in birth rates and travel costs. The values of the different objective functions changed little under the alternative objective functions. However, changes in the assumptions affecting the aggregate level of demand caused changes in the objective functions of considerable magnitude. The alternative objective functions mainly caused shifting between specialized service centers. The estimation of future usage and the evaluation of the feasibility of a facility replacement or expansion decision is the potentially most valuable use of the model to the health planner. This value is enhanced by the models' use of data which health planners have at their disposal and ought to include in the decision process anyway.

more loosely than the others. However, it is hoped that the discussion below will enable the formation of judgments on the conditions under which generating techniques or goal-programming procedures are favored according to this criterion. The treatment begins with GP and the difficulty of setting weights and targets and leads naturally to a discussion of human choice theory and its implications for the possibility of the setting of such weights as well as of evaluating the results of the generating technique. Next, the implications of naively setting such values are suggested. Finally, the generating techniques are considered as a means for facilitating the search for the preference structure of the decision maker.

The GP approach can be an extremely useful tool for situations in which the DM often commands the system in question (e.g., many private sector decisions) and where the DM generally has a clearer notion of targets and priorities. It is less so for situations frequently characterized by a relatively complicated system or process of decision making in which no individual is capable of setting targets. Public projects, for example, are seldom developed with specific targets of the objectives in mind; that it is generally relative, rather than absolute, levels of objectives which are of primary importance.

Furthermore, for the GP the DMs are expected to quantify targets and weights without the information on trade-offs contained in the noninferior set and are presumed to be in possession of a multiattribute utility function which is separable, additive, and stable over decision iterations. Not only is this a restrictive specification of the utility function, it is unlikely that this preference structure is completely known by the DM. In combination with the results of a great deal of research in psychology indicating a rather limited information processing capacity of the human brain, this suggests that the DM may have great difficulty in articulating weights (w_i) associated with the various objectives. Morse (1976) provides a useful summary of the human choice theory literature, featuring such main works as Thurstone, Luce, Coombs, Tversky, and Keeney and Raiffa.

In brief, the literature suggests that choosing is difficult, that large amounts of data aggregate poorly and are associated with trade-offs (weights) that are unstable over time, and that they are not representable by separable additive utility functions. As Zeleny argues, these weights are not a priori in the possession of the DM. Rather, they are, or should be, learned through the decision process and are not independent of the set of feasible alternatives.

Given these difficulties with assigning weights to objectives on the part of a DM, what are the implications of "second best" assignments of weights? The practice of placing highest weights on the most important objectives, and vice versa, results in what Morse (1977) terms "naive weights." As it turns out, it is very hard to predict how these weights will drive even a linear system in a GP context. Indeed, Morse devised numerical examples which showed little correspondence between priority weights and goal attainment. Increasing a priority weight on objective i may lead in fact to a lower attainment of the ith goal.

Sensitivity analysis is complicated in goal programming in part because the actual decision variables have zero coefficients in the objective function; and this information makes its way into the objective function only indirectly through the right-hand side (T_i) of the policy constraints (Morse). These goal constraints (14) have both surplus (d_i) and slack (e_i) variables, and these variables are driven by a set of dependent objective function coefficients, so that for one to change at least one other must change as well. This is because weights are usually set to insure convex combinations by making them sum to one. Even without this restriction, adjusting a single weight alters the relative relations of the w_i.

Of course, the same set of findings of information processing limitations in humans which makes it difficult to set weights and targets a priori also makes it difficult to make a final decision when confronted with the great volume of information supplied by generating techniques. Clearly, the case can be made that the vast quantities of information associated with a problem of many objectives may so baffle the DM, that the decision based on a GP approach with naively set weights and targets may be as sensible as, or more so than, a decision resulting from the information overload of a generating technique. In this regard, pruning procedures (automated elimination of a subset of solutions) may be of value (see Morse 1977).

If the "overload" problem is not too severe, the DMs in a generating technique context are

aided in their search for the preference structure by being supplied pairs of noninferior feasible alternatives, the objective values, and trade-offs and being asked to compare these solution pairs (Coombs). The generating technique, in contrast to the GP structure, offers an intuitive approach to the problem. It leaves to the computer what it does best (generating alternatives) and to the DMs what they do best (evaluating pairs).

Summary

While multiple objective decision-making approaches are not new, they have only recently begun to be used operationally. In the agricultural economics applications, variations of goal programming or lexicographic programming seem to predominate. Neely, North and Fortson provide a good example of the use of goal programming in a recent issue of this *Journal*.

Goal programming succeeds in reducing computational requirements by requiring of DMs value judgment on targets for each goal (absolutes, not relatives) as well as weights on deviations from these targets. This is done without the benefit of knowledge of the feasible alternatives and trade-offs. Several studies in psychology show the difficulty of setting weights on deviations from targets (knowing one's preference structure), and indeed it was noted that GP weight setting implies a very restrictive form of utility function. Given this limitation, recourse to naive weights often follows. Morse's 1977 work shows that if naive weights are used, the system may be driven in counter-intuitive and inferior ways.

Goal programming is clearly superior to generating techniques on the basis of computational ease and expense—indeed, as the number of objectives increases beyond, say, four, the computations required in the generating techniques become extreme. However, the generating techniques fared relatively better by the other three criteria: trade-offs were explicit, maximum amount of information was provided, and the interaction between DM and analyst was on a logical and sound basis.

In short, multiple objective methods likely will grow in importance in empirical applications. Generating techniques may become the most important of these approaches because of their intuitive basis, the explicit quantification of trade-offs they supply, and the assistance to the learning process they provide. Goal programming may prove more useful for situations characterized by many objectives, and cases in which the DM has a good handle on target levels, weights on deviations, and the system in question (and this knowledge is much more likely to be held in private than in public sector problems).

Finally, it merits restating that in the interest of length, the interactive multiple objective procedures have not been discussed here. These approaches can prove valuable in many decision settings and can be combined with basically generating-type techniques, as in Candler and Boehlje, as well as with GP applications, as in Monarchi, Weber and Duckstein. Wallenius provides a summary and comparison of interactive techniques.

Appendix

GP as a Generating Technique

The comparisons made earlier were of generating techniques with GP as it is generally used (*viz.*, as a technique which uses a previously articulated set of preferences). Haimes, Hall, and Freedman (p. 25) indicate that, "just as in the parametric case, the noninferior set can be generated by varying the weighting factors, but it can be shown that this method suffers from the same duality gap problem as the parametric approach when the problems are nonconvex." The "parametric case" to which they refer is what we have called the weighting method. The presence of this duality gap (an inability to generate all noninferior solutions in the nonconvex case) has been proven

by Gembicki. It is shown below that if the purpose of the analyst is to investigate the noninferior solution space, GP can be used in the same way as the weighting method. In fact, arguments made previously suggest that for this purpose, the constraint method is generally more practical.

To show that GP is equivalent to the weighting method, rewrite (14) as

$$-d_i + e_i = T_i - z_i(\mathbf{x}), \tag{17}$$

and substitute (17) into (11), producing

$$\min \sum_{i=1}^{k} w_i[T_i - z_i(\mathbf{x})], \text{ or} \tag{18}$$

$$\min \left[\sum_{i=1}^{k} w_i T_i - \sum_{i=1}^{k} w_i z_i(\mathbf{x}) \right]. \tag{18$'$}$$

Because $\sum_{i=1}^{k} w_i T_i$ is a constant, minimization of (18)′ is equivalent to minimization of $\sum_{i=1}^{k} w_i[-z_i(\mathbf{x})]$. Thus, the GP problem can be expressed as

$$\max \sum_{i=1}^{k} w_i[z_i(\mathbf{x})], \tag{19}$$

subject to (12)–(15), which is precisely the weighting method model (4)–(6) with the constraints (14) and (15) added.

Measuring the Indirect Effects of an Agricultural Investment Project on Its Surrounding Region

C. L. G. Bell and P. B. R. Hazell

Agricultural investment projects may generate important downstream benefits for the regions in which they are located. Using a semi-input-output model of the regional economy, an attempt is made to quantify the downstream benefits generated by an irrigation project in Malaysia. In aggregate the project's downstream effects on regional income were of an order similar to its direct effects, but the main beneficiaries of the downstream benefits were the nonfarm households. Each dollar of downstream income probably was supported by just over a dollar of additional investment in the local economy.

Key words: growth linkages, input-output analysis, Malaysia, project appraisal, regional development.

Investment projects may generate substantial indirect effects, or pecuniary external economies, as Scitovsky would call them. These effects stem partly from production linkages. First, the project will generate demands for investment and intermediate goods. Second, the rise in output due to the project may cheapen supplies to other sectors, and so increase the profitability of new investment in those sectors, a case which has been analyzed extensively by Chenery. But consumption linkages also come into play if the extra income flowing from the project boosts the level of final demand in the economy. Hirschman, in arguing for the relative neglect of agriculture in development strategies, discounted the value of these linkages for agricultural investments. Recently, however, both Mellor and Johnston and Kilby have renewed debate on the importance of these linkages for economic growth in developing countries, with Mellor laying particular stress on the importance of final linkages arising from increases in agricultural incomes.

It is also of interest to ascertain how the indirect (or "downstream") effects of a project affect the distribution of incomes. For example, while an agricultural project may generate a strong rise in the incomes of all farm households, the resulting downstream benefits may be reaped by richer nonfarm households. There is also a regional dimension to this issue. Suppose an agricultural project produces powerful downstream effects upon its surrounding region, which was previously poor. Then, as Mellor has emphasized, income disparities among agricultural regions will be increased all the more, even though the income gap between industrial regions and that receiving the project will narrow.

Another consideration is that knowledge about the structural sources of downstream effects could be useful in improving the design of integrated regional development strategies. In particular, if the structure and relative strength of linkages are known, then public policy can attempt to see that such linkages function without friction.

In this paper we propose and apply an approach to measuring the magnitude and incidence of regional downstream effects, based on a social accounts matrix (Pyatt et al.) and a variant of Tinbergen's semi-input-output method. We begin by sketching the main features of the Muda River project and surrounding region in northwestern Malaysia, the sub-

Srinivasan, and two anonymous referees for helpful comments on earlier drafts, while exempting them from all surviving errors. Special thanks are also due Roger Slade for helpful discussions about many of our data assumptions. The views expressed here are those of the authors and do not necessarily reflect those of the World Bank.

ject of our empirical application. Next, we discuss the considerations influencing our choice of methodology and then present the semi-input-output model on which the quantitative analysis is based. Subsequently, we use this model to estimate the direct and indirect effects of the project at maturity (in 1974) on output and incomes in the regional economy. In so doing, we also estimate both the pace and pattern of the region's growth over the period 1967–74 and those which would have occurred in the hypothetical event that the project had not been undertaken. Finally, we provide some sketchy estimates of all the balancing investments needed to support the downstream incomes generated by the project.

The Project and Its Region

The project involved a total investment over the period 1967–73 of about $270 million in the form of dams, a canal system, feeder roads, and drainage infrastructure for the irrigation of 240,000 acres of paddy land.[1] Before irrigation, a single paddy crop was grown each year in harmony with the rainfall pattern. Double cropping followed irrigation, and the accompanying introduction of quicker maturing, fertilizer-responsive varieties also has increased yields. The incomes of the 51,000 farm households in the project's command area almost doubled over the period 1967–74, and the region claimed new prominence as the supplier of some 40% of Malaysia's annual rice requirements. Nevertheless, the region is still relatively poor, with a per capita gross domestic product in 1972 of $600 compared to $1100 for Malaysia as a whole.

The basis for the spatial definition of the regional economy is discussed in a United Nations FAO/IBRD Report (pp. 22–24). In brief, the region encompasses the whole of the state of Perlis and about half of Kedah. It comprises the irrigation command area, a further 70,000 acres of low-lying, rain-fed paddy land, and a fringe area made up mostly of rubber smallholdings. The region's population was 687,100 in 1972, 16% of whom were resident in towns with 5,000 people or more, and 81% lived within the boundaries of the irrigation command area.

We have distinguished between five household classes to reflect the income distribution aspects of regional activities. Our definitions rest on socioeconomic criteria: in particular, endowments of labor and land, access to irrigation, and sector of employment. The three agricultural household classes within the project area are: (*a*) "landless" households, which derive most of their income from employment on other paddy farms; (*b*) "labor abundant" farm households, which possess a high ratio of family labor to area operated; and (*c*) "land abundant" households, which hire in substantial amounts of nonfamily labor. Clearly, the household's endowments of land and labor are connected intimately with its labor market transactions, which underlie the definitions adopted here.

Farm households outside the project area are engaged heavily in "other agriculture" as well as the production of rubber and/or unirrigated main season paddy. They also supply labor to households in the project area at the times of peak activity in paddy cultivation. As their economic activities are different from those of farm households within the project area, and there is an intrinsic interest in what happens to households outside, but on the periphery of, large development projects, they merit the status of a separate household category.

Nonfarm households account for 35% of the region's population, and they display wide variations in income and wealth. Ideally, therefore, they should be subdivided into further categories. However, data to place them in more refined classes were lacking. A majority of nonagricultural households are ethnic Chinese, who generally enjoy higher per capita incomes than the predominantly rural Malays. A summary picture of population and incomes for these classes in 1972 is set out in table 1.

The region's production structure was disaggregated into the thirty-five sectors listed in table 3. These definitions are generally straightforward. Cases arose where two or more sectors produced the same commodity. This happened because either the commodity was produced under different institutional arrangements with important differences in technology and/or in the distribution of sectoral value added among households, e.g., small and commercial rice mills, or because the commodity took different forms according to its end use or type of demand it could sat-

[1] All monetary values are in 1972 Malaysian dollars unless otherwise indicated.

Table 1. Socioeconomic Characteristics of Household Classes in 1972

	Landless Paddy Workers	Labor-Abundant Paddy Farms	Land-Abundant Paddy Farms	Other Agricultural Households	Nonfarm Households	All Households
Number of households	4,367	18,045	33,426	25,333	44,047	125,239
Number of persons (thou.)	21.3	103.3	184.7	131.8	246.0	687.1

isfy, e.g., road and rail transport, residential and nonresidential construction.

Methodological Considerations

Two considerations bore heavily on our choice of methodology. First, to capture adequately the effects flowing from interindustry and final demand linkages between agriculture and the rest of the economy, some degree of sectoral disaggregation may be necessary. Also, the evidence on household expenditure and savings behavior suggests the need to disaggregate households by income levels. These considerations can be accounted for at any point in time through the construction of a social accounting matrix (SAM). In the present case, sufficient data were at hand to construct a detailed regional SAM for 1972 (Bell et al.)

Second, because a project's implementation is almost invariably accompanied by changes in the levels of regional activities which owe nothing to the advent of the project, e.g., technical change, autonomous private investment, and government spending, a correct analysis of its impact at maturity requires construction of a "picture" of how the economy would have looked in the absence of the project. Pictures of the economy may also have to be constructed for the pre- and/or post-project situations if sufficient primary data are not available for the estimation of SAMs for the years in question. In constructing these pictures, the most important assumptions concern the choice of exogenous variables. For each sector one must decide whether output or final demand is to be fixed exogenously. This led us to a variant of the semi-input-output method, which can accommodate a choice between inelastically fixed supply and inelastically fixed demand in each sector—unlike the standard formulation of the closed Leontief system, in which the complete bill of gross outputs follows solely from the set of final demands.

A Semi-Input-Output Model

Beginning with the set of material balances, we have

$$(1)\qquad X_i = \sum_{j=1}^{n} a_{ij}X_j + \sum_{k=1}^{h} C_{ik} + J_i + E_i,$$

there being n commodities (sectors) and h types of household; X_i denotes the gross output of sector i, a_{ij} the input of commodity i needed to produce a unit of commodity j, C_{ik} the expenditure of household class k on commodity i, J_i the deliveries of good i to investment activities, and E_i the net exports of good i.

The gross income of each household class is made up of direct earnings in commodity production and distributed profits from incorporated enterprises plus net transfers (R^*_k) from other household classes and abroad. The first two are taken to be proportional to gross output, whereas the latter are assumed to be exogenous. Choosing physical units of measure such that all commodity prices are unity, we have

$$(2)\qquad Y_k = \sum_j \omega_{kj}X_j + R^*_k.$$

The claims on such incomes are taxes, savings, and consumption expenditures. The tax schedule is assumed to be linear in income

$$(3)\qquad T_k = t_kY_k + T^*_k.$$

Savings are assumed to be proportional to disposable incomes,

$$(4)\qquad S_k = s_k(Y_k - T_k),$$

as there were no data to warrant a more com-

plicated form. Finally, household class k's expenditure on good i is assumed to be a linear function of its total outlays on consumption,

$$C_{ik} = \gamma_{ik} + \beta_{ik}C_k. \tag{5}$$

Here we must enter a qualification concerning household's purchases of the outputs produced by government sectors. Households may make small cash outlays on some services, such as education and health, but their overall consumption of government services depends on the size of (exogenous) government expenditures and administrative "access" rather than disposable income. Hence, the relevant C_{ik} are fixed in relation to the corresponding gross output levels quite independently of the household's income-outlay identity: $Y_k \equiv T_k + S_k + C_k$. However, to preserve the latter, the actual cash outlays on government education and health must then be treated as taxes, the relevant γ_{ik} and β_{ik} being absorbed into T^*_k and t_k, respectively.

Substituting (3), (4), and (5) into (1), and combining the result with (2), we obtain the following more compact system:

$$\left[\begin{array}{c|c} I - A & -Bc \\ \hline -\Omega & I \end{array}\right]\left[\begin{array}{c} \mathbf{X} \\ \hline \mathbf{Y} \end{array}\right] = \left[\begin{array}{c} \Gamma\mathbf{u} \\ \hline \mathbf{0} \end{array}\right] - \left[\begin{array}{c} B(I - s)\mathbf{T}^* \\ \hline \mathbf{R}^* \end{array}\right] + \left[\begin{array}{c} \mathbf{J} \\ \hline \mathbf{0} \end{array}\right] + \left[\begin{array}{c} \mathbf{E} \\ \hline \mathbf{0} \end{array}\right], \tag{6}$$

where A denotes the $n \times n$ matrix (a_{ij}); B, the $n \times h$ matrix (β_{ik}); c, the $h \times h$ diagonal matrix whose elements are $c_k = (1 - s_k)(1 - t_k)$; Γ, the $n \times h$ matrix (γ_{ik}); $\mathbf{E}$, the $n \times 1$ vector (E_i); $\mathbf{u}$, an $h \times 1$ vector of ones; $\mathbf{J}$, the $n \times 1$ vector (J_i); $\mathbf{R}^*$, the $h \times 1$ vector (R^*_k); s, the $h \times h$ diagonal matrix (s_k); $\mathbf{T}^*$, the $h \times 1$ vector (T^*_k); $\mathbf{X}$, the $n \times 1$ vector (X_i); $\mathbf{Y}$, the $h \times 1$ vector (Y_k); Ω, the $h \times n$ matrix (ω_{kj}).

Equation (6) is written in the standard closed Leontief form, which solves for all gross outputs and household incomes given the levels of exogenous demands—in this case, deliveries to investment activities and net exports. For some purposes, however, this may not be an appropriate statement of the problem. As we are concerned with the indirect effects of a project, we want household incomes to be endogenous. But in each of the n material balances, we are still free to fix any two of gross output, deliveries to investment and net exports, leaving the third to be determined endogenously; for the system remains linear in $(n + h)$ equations and $(n + h)$ unknowns.

In what follows, investment deliveries are assumed to be exogenously determined by entrepreneurs' "animal spirits" and/or the government's development expenditure programs. This is a departure from previous applications of semi-input-output, which focus on the "complementary bunch" of investments which must take place in the nontradable sectors to support a given increase in the output of a particular traded good—see, for example, Kuyvenhoven. Although our choice is dictated by the absence of data from which a full investment matrix could be estimated, it is still necessary to check, if only in a sketchy way, that the stream of exogenously specified investment deliveries is consistent with the changes in output levels that occur over the relevant period.

This treatment of investment implies that the final choice for "closing" the economic system is between fixing domestic supply (gross output), and fixing net foreign demand (exports). In making this choice, there are two general considerations. First, we may wish to create a fairly comprehensive set of social accounts for some year in the past for which we have only fragmentary information, on the assumption that the parameters of equation (6) estimated from the social accounts of some "base year" are stable. Estimates of exogenous taxes ($\mathbf{T}^*$), transfers ($\mathbf{R}^*$) and investment deliveries ($\mathbf{J}$) for the earlier year are needed. But when it comes to choosing between gross output and net exports, the search for data is eased by recognizing that sectors producing nontraded goods and services must have zero net exports. As for the remaining sectors, piecing together a set of estimates of gross output levels commonly will be a less speculative exercise than doing so for net exports—in the context of a regional economy, at least.

Second, we may be interested in forecasting or in simulating some hypothetical circumstances, such as the absence of the project. Here, whether gross output levels or net exports are made exogenous is not a matter of convenience or reliability in estimation, but rather of one's view as to how the economy works. In the present context, the output trajectories of some tradables are exogenous, having been fixed by decisions made in the past. In these circumstances, net exports must do the adjusting. However, sectors producing nontradables are faced with additional demand from firms and households, and so their outputs will expand also, either by fuller capacity

utilization or, if enough time is allowed, by additions to existing capacity. But excess capacity or not, the key assumption is that the production of nontradables takes place at constant costs, which implies that short-period supply bottlenecks, and hence the rises in prices which accompany them, are ignored. In this respect, the analysis set out is in keeping with the general recommendations concerning the treatment of nontradables offered, e.g., Little and Mirrlees.

The foregoing discussion can be translated into a simple, comparative static account of the development of a regional economy in which the source of growth is the expansion of the primary sector. In each "period," the supply of output from this sector is fixed, and the region faces a perfectly elastic "foreign" demand curve for its products. By contrast, the supply of nontradables is perfectly elastic, and foreign demand for these goods is perfectly inelastic (at zero).

Let the subscripts T, D, and N denote, respectively, the following sets of sectors: tradables, distributive and transport services, and other nontradables. Noting that the set of endogenous variables is the vector ($\mathbf{E}_T$; $\mathbf{X}_D$; $\mathbf{X}_N$; $\mathbf{Y}$), equation (6) can be rearranged as

$$
(7)\quad
\begin{bmatrix} -I & -A_{TD} & -A_{TN} & -B_{TC} \\ -\mu_{DT} & I - A_{DD} & -A_{DN} & -B_{DC} \\ 0 & -A_{ND} & I - A_{NN} & -B_{NC} \\ 0 & -\Omega_D & -\Omega_N & I \end{bmatrix}
\begin{bmatrix} \mathbf{E}_T \\ \mathbf{X}_D \\ \mathbf{X}_N \\ \mathbf{Y} \end{bmatrix}
=
\begin{bmatrix} \Gamma_T u \\ \Gamma_D u \\ \Gamma_N u \\ 0 \end{bmatrix}
+
\begin{bmatrix} J_T \\ J_D \\ J_N \\ 0 \end{bmatrix}
-
\begin{bmatrix} B_T(I-s)T^* \\ B_D(I-s)T^* \\ B_N(I-s)T^* \\ 0 \end{bmatrix}
+
\begin{bmatrix} -I + A_{TT} & 0 & 0 & 0 \\ A_{DT} & 0 & \mu_{DN} & 0 \\ A_{NT} & 0 & I & 0 \\ \Omega_T & 0 & 0 & I \end{bmatrix}
\begin{bmatrix} \mathbf{X}_T \\ \mathbf{0} \\ \mathbf{E}_N \\ \mathbf{R}^* \end{bmatrix},
$$

where μ_{DT} and μ_{DN} are the matrices of distributive and transport margins on the net exports of tradables and nontradables, respectively.[2]

[2] It may happen that some sectors face completely inelastic, albeit positive, "foreign" demand. In that case, they are producing nontradables at the margin and are treated as such in the analysis, the vector of these foreign demands being $\mathbf{E}_N$. It should be noted also that distributive and transport margins are earned on gross rather than net flows, so that the formulation in equation (7) is strictly correct only when there are no competitive imports for those sectors which export. In the empirical application pursued below, that is a defensible approximation to the observed trade patterns.

Equation (7) is the semi-input-output model from which our empirical results were derived.

The Growth of the Regional Economy: 1967–74

Before embarking on a discussion of how the exogenous variables and their values were chosen, two important implicit assumptions in our use of equation (7) should be noted. First, the effects of changes in the structure of relative prices were ignored, although in fact the region's barter terms of trade worsened slightly between 1967 and 1972, before improving strongly over the next two years. But if relative prices are changing, equation (7) will be free of error in generating real value added (measured in units of own output) if, and only if, intermediate inputs form a Cobb-Douglas aggregate in each sector. And even then, there are likely to be substitution effects in household expenditure patterns. It should be noted also that while the exogenous quantity flows that drive (7) are those which occurred at the prices which actually ruled (at one time or another), all inputs and outputs are valued at base year prices. Hence, changes in the barter terms of trade are not allowed to alter the levels of real incomes through the usual effects of changes in prices on nominal value added; they do so only through their effects on the output of tradables. The only alternative to making a foray into the difficult terrain of price endogenous systems is to take the position that these blemishes are the price to be paid in using a tractable system such as (7).

Second, with the two following exceptions, it was assumed that the structural parameters of equation (7) also remained stable in the face of all other influences. First, there were the changes in paddy production technology and the distribution of the sector's value added following the introduction of irrigation and new paddy varieties. Second, there have been changes in the region's population and in the pattern of seasonal migration associated with paddy cultivation.

Where the paddy sector is concerned, the estimates of the technology ($\mathbf{A}_6$) and distribution (Ω_6) vectors are derived largely from a programming model which predicts inputs, output, land rents, and wages, given certain resource endowments and the prices of tradables. The important changes in technology between 1967 and 1974 were the substitution of

mechanical for animal draught power and the more intensive use of fertilizer on new, high-yielding varieties. There was also a marked increase in the proportion of value added paid as wages to migrant laborers from the non-project area and other regions, although the real wage rate rose only slightly. The distribution of value added among households underwent more radical changes, the most noteworthy being the fall in the share of nonproject farm households, which continued to cultivate a single crop, although they did benefit from additional wage earnings within the project area. The shares of output paid as wages to workers from landless and nonfarm households both increased somewhat, while that paid as rents (some of which accrued to rentiers among nonfarm households) stayed virtually constant. These shifts are presented in summary form in table 2.

As for population growth, this affects the demand system by altering the intercept terms, i.e., the $\{\gamma_{ik}\}$, though leaving the marginal expenditure proportions $\{\beta_{ik}\}$ unchanged.[3] The only population data available are contained in the two censuses of 1957 and 1970. The quinquennial growth rates for these two subpopulations were 4.6% and 3.7%, respectively. These rates are assumed to hold for the period 1967–72, because only after 1971 did farm incomes begin to rise strongly in response to the arrival of irrigation; and expectations about alternative income levels, which figure heavily in the decision to migrate, are unlikely to have been revised sharply in the immediate aftermath. It seems plausible that the surge in real incomes between 1971 and 1974 should have done something to stem the outflow of permanent migrants from the region. But in the absence of any evidence, we were reduced to guessing that the farm and nonfarm populations were rising at 1% and 2% per annum, respectively, between 1972 and 1974.

Exogenous Variables for 1967

Recall that an attempt to construct a detailed picture of the economy as it was in the past need take account only of data availability when it comes to choosing between fixing export or output levels for each sector. The sectors comprising the agricultural complex (1–11) all produce tradable goods. With the exception of sector 10, it was possible to derive estimates of gross output. Fortunately, in the case of sector 10, there were relevant data for estimating exports in 1967. The only other sector producing tradables is (14), and once again data were available on its export components. In the remaining sectors, of course, net exports were set at zero, although it should be noted that the output levels of the four government sectors are known and given independently of demand.[4] Deliveries to investment activities are made only by sectors 10, 14, 26, and 27. Again, the sources for the 1972 estimates provided the data for their 1967 counterparts. Of the remaining exogenous variables, net private transfers to households were set at their 1972 levels, these being very small and there being no other basis for a set of

[3] In period t, the expenditure of the kth class of household on the ith commodity is

$$C_{ik}(t) = \gamma_{ik} + \beta_{ik}C_k(t).$$

If the population grows by g_k percent and expenditure per family stays constant, then $C_{ik}(t)$ grows by g_k percent also. If, however, the population is stationary and expenditure per family grows by ϵ_k percent, then

$$C_{ik}(t+1)|_{g=0} = \gamma_{ik} + \beta_{ik}(1+\epsilon_k)C_k(t).$$

Combining the two, we get

$$\begin{aligned} C_{ik}(t+1) &= (1+g_k)\gamma_{ik} + \beta_{ik}[(1+g_k)(1+\epsilon_k)]C_k(t) \\ &= (1+g_k)\gamma_{ik} + \beta_{ik}C_k(t+1). \end{aligned}$$

[4] To be exact, they are completely independent of household incomes, but slightly dependent on activity levels in other sectors through weak interindustry linkages. The allocations to households are given exogenously and the (small) supplies to satisfy interindustry demands are endogenously determined.

Table 2. Household Shares in Gross Output from the Paddy Sector (Ω_5)

Household Class	1967	1972	1974	1974[a]
1 Landless	0.0179	0.0190	0.0207	0.0168
2 Labor abundant	0.1436	0.1442	0.1499	0.1451
3 Land abundant	0.4658	0.4675	0.4859	0.4705
4 Nonproject farm	0.1846	0.1188	0.1138	0.1710
5 Nonfarm	0.0475	0.0540	0.0590	0.0460
Total	0.8594	0.8035	0.8293	0.8494

[a] In the absence of the project.

1967 estimates. Finally, "exogenous" taxes (T^*_k) on households were estimated in the same way as for the 1972 SAM. These taxes take the form of licenses, fees, and duties, and are levied independently of income levels.

Exogenous Variables for 1974

The relevant sectoral outputs, exports, and investment deliveries were estimated in similar fashion to those for 1967. It also should be noted, however, that the treatment of sawmilling for 1974 differed from that for 1967 in that net exports were set at their 1972 level. This choice reflects the fall in the volume of Malaysia's timber exports during the 1974 world recession and accords well with the views expressed by local businessmen. In effect, then, the output of this sector in 1974 was demand-driven. Net private transfers were kept at their 1972 levels, and exogenous taxes on households were estimated on the same basis as before.

The Results

These values of the exogenous variables generate the salient flows in the economy during 1967 and 1974 which are set out in tables 3 and 4, along with their counterparts from the 1972 SAM. Gross output rose by 55% over the seven-year period, the largest absolute contribution being made by the paddy sector, which accounted for about 21% of the total in 1974. Regional value added grew slightly faster than gross output, as output increased at

Table 3. Regional Gross Output and Value Added in 1967, 1972, and 1974 ($10,000 in 1972 Prices)

[a] In the absence of the project.

a greater-than-average rate in large sectors which have a high ratio of value added to gross output, such as paddy, smallholder rubber, and government. At a more disaggregated level, gross output from the agricultural complex expanded by 70%, noteworthy details being a doubling of paddy production, big jumps in smallholder rubber output (8) and rubber processing (9), and the fact that small-scale rice mills expanded output much more rapidly than commercial ones. Elsewhere in the economy, there were broad gains in transport (15, 16), services and distributive trades (17–22), and utilities (23–25). Residential construction (26) boomed, but there was a steep decline in nonresidential construction (27) as work on the Muda irrigation project tailed off from its 1968 peak. Current outlays by government (28–31) increased substantially.

In aggregate, household incomes grew by just over 7.5% per annum between 1967 and 1974. This rapid rate also was accompanied by significant shifts in income distribution. The incomes of all households in the project area grew at about the same rate. A more rapid growth of incomes accruing to landless households from paddy production was offset by a proportionally larger gain in income from nonpaddy sources accruing to the two classes of "landed" households in the project area. Farm households outside the project boundary were less fortunate, being heavily dependent on a single crop of unirrigated paddy and wage employment in the project area. However, the sharp rise in rubber output from smallholdings kept their incomes growing at a fair rate. The incomes of nonfarm households grew at only two-thirds of the rate enjoyed by farm households in the project command area, but still accounted for 57% of aggregate household incomes in 1974.

Autonomous Growth and the Impact of the Project

Beginning with the accounting, denote the vector $[\mathbf{X}, \mathbf{Y}]$ by $\mathbf{Z}$, and let $\mathbf{Z}^\circ$ stand for the vector of gross outputs and household incomes in the absence of the project. We have the identity

$$(8)\quad \mathbf{Z}_{1974} - \mathbf{Z}^\circ_{1974} \equiv (\mathbf{Z}_{1974} - \mathbf{Z}^\circ_{1967}) - (\mathbf{Z}^\circ_{1974} - \mathbf{Z}^\circ_{1967}).$$

The left-hand side is the net impact of the project in 1974. The first term on the right-hand side is the change in $\mathbf{Z}$ between 1967 and 1974 in the hypothetical event that there had been no project construction work in 1967; and the second term is the set of "autonomous" changes in the regional economy over the period, i.e., the changes that would have occurred had there been no project. Thus, to examine the sources of growth in a "causal" way, we must construct hypothetical pictures of the economy for both years.

1967 without the Project

It may seem that we have complicated the task unnecessarily by choosing a starting year in which project construction was already underway; but the defense is a simple one. The data set on which exogenous variables would be based is very sketchy for earlier years, and we think it better to rest our (minor) hypothetical modifications to 1967 on the relatively secure foundations of the estimated "actuals" than to estimate "actuals" for 1965 (say) on a far shakier data base. We arrived at our hypothetical picture of 1967 by making a change in one exogenous variable of the set generating $\mathbf{Z}_{1967}$: investment deliveries by sector 27 were cut by \$40 million, the dif-

ference being the direct construction demands of the project in that year.

It is worth emphasizing the assumptions which implicitly accompany this change. First, the outputs of sector 1–9 in the agricultural complex are held fixed at their actual levels in 1967, which implies that they were unaffected by the demand for factors arising out of project construction work. This boils down, in essence, to assuming that labor was in perfectly elastic supply, an assumption made plausible by the heavy outmigration from the region between 1957 and 1970. Second, it is unlikely that current government outlays (28–31) would have changed from their 1967 levels. Third, in the cases of the remaining sectors, whose output is demand-driven, there is no problem of output capacity because a cut in exogenous demand will reduce output levels. Fourth, private transfers and lump sum taxes have been left alone. Estimates of the formers' 1967 "actual" values are already tenuous. License fees for vehicles and businesses might have been a little lower in the absence of project construction work, but it is difficult to gauge by how much. Last, a more subtle point: if there had been no construction work on the project, expectations about the future may well have been different, perhaps with important consequences for private investment. This, too, has been skipped over; the error, if any, would be in the direction of overstating regional activity levels and incomes in the hypothetical version of 1967 presented below.

1974 without the Project

The departures of the hypothetical exogenous variables from their actual values in that year are naturally more extensive. The most important of them is, of course, the level of paddy output. The small increase over the 1967 level is largely a reflection of improvements in yields of the main season crop, which would have occurred even if the project had not been undertaken. As for the sector's production technology, compared with 1967 there is no advance in mechanization but more intensive use of agrochemicals. The small declines in the shares in value added of households supplying labor to cultivating households are the result of a slight fall in the paddy wage measured in units of paddy, the nominal wage rate having risen more slowly than the price of paddy but faster than that of the relevant consumption basket.

As the region supplied about 40% of Malaysia's rice needs in 1974, one might also ask whether the price of paddy would have risen even more strongly if the project had not been undertaken. However, the country's source of marginal supplies was imports, principally from Thailand and China, and it does not seem likely that the domestic price, which was close to the c.i.f. price of imports in 1974, would have risen further if there had been no Muda project.

In the agricultural complex, the gross output levels of the two rice-milling sectors have been left at their 1967 levels. As the output of paddy would have increased modestly in the absence of the project and there were small net imports of paddy into the region in 1967, this assumption seems sound. The gross output levels of sectors 3, 4, 6, 7, and 9 were set at their actual values in 1974, which amounts to assuming that, on balance, activity in these sectors was unaffected by the increased demand for domestic factors and goods generated by the project. In the case of smallholder rubber, however, some allowance was made for the fact that seasonal work in paddy production competes with rubber tapping. The level of net exports from sector 10 would have been somewhat lower in the absence of the project. For after 1970, the buffalo herd was being run down rapidly in the face of the advances in mechanization which accompanied the project, and this resulted in an increased supply of animals on the hoof for export. To reflect this, the sector's net exports were set $0.6 million lower than their actual level in 1974. In keeping with the argument in the previous section, net export deliveries from sawmilling were left unchanged at their actual value in 1974. Both the exports of sector 14 and government outlays (29–31) were also left at their 1974 levels.

Turning to investment activities, an inspection of the time series of buffalo livestock between 1967 and 1973 led to a "guesstimate" of zero deliveries from sector 10 to investment activities in 1974 in the absence of the project. Deliveries from sector 14 and government investment in housing were taken as given, but private investment in urban housing was reduced by about 50% to reflect the likely reduction in the demand for urban housing services had the project not been undertaken. Investment in rural housing was derived from the

Table 5. The Composition of Changes in Per Capita Household Incomes Due to the Project ($)

Source of Income Change	Household Class 1	2	3	4	5	Total
Paddy						
output effect	66	108	195	45	15	95
distributive effect	27	8	16	−19	8	−6
Other	9	15	17	13	107	50
Total	102	131	230	37	130	139

expenditures of single-cropping households in 1972. In the case of nonresidential construction, the tail end of Muda project work was cut out, together with a sizable chunk of the (modest) private demand for such output.

Following earlier practice, private transfers were left at their actual levels in 1974. Lump sum taxes were altered to reflect "guestimates" of what the stock of vehicles and the number of businesses would have been in the absence of the project. These changes affected mainly nonfarm households, reducing their tax burden by almost $4.5 million.

The only remaining issue is whether permanent outmigration from the region might have been higher if there had been no project. Although there is no direct evidence on which to base an answer, it seems plausible that the rapid rise in incomes between 1970 and 1974 has induced more people to stay in the region than otherwise would have been the case. In rough and ready fashion, it has been assumed that the farm population would have been stationary after 1972, whereas the nonfarm population would have grown at 0.5% per annum.

The Results

We begin with the net impact of the project at maturity, viz., $\mathbf{Z}_{1974} - \mathbf{Z}^{\circ}_{1974}$, laid out in tables 3 and 4. Regional gross output is about a third higher, fuelled largely by rises in paddy and rice-milling output. Taken as a whole, the agricultural complex accounted for about 70% of the project's net impact on aggregate gross output. For the "demand-driven" group, the heaviest absolute increases occur in sectors 15, 17, 21, 26, 27, 34, and 35. The gain in regional value added due to the project is about 30% of what total value added would have been in the absence of the project. As the absolute gain is $117.5 million, of which $67 million is due to the increase in paddy output, then for every dollar of value added generated directly by the project at maturity, another 75¢ was generated in the form of "downstream" or indirect effects. Within the project boundary, households enjoyed large income gains from the advent of irrigation; farm households on the region's periphery gained somewhat from additional seasonal work in paddy cultivation; and nonfarm households did rather well, especially out of the income-expenditure linkages of the system.

It is also of some interest to decompose the total change in income due to the project at maturity into that derived from paddy production and that from all other sources. And within the former, we distinguish between the pure output effect on incomes assuming that the actual 1974 distribution of value added held in the absence of the project and a distributive effect resulting from changes in the distribution vector Ω_5, where the "distributive" effect is defined as follows: the incomes of household class k from sector j in the two situations are $\omega_{kj}X_j$ and $\omega^{\circ}_{kj}X^{\circ}_j$, respectively. The "output" effect is simply $\omega_{kj}[X_j - X^{\circ}_j]$, and the "distributive" effect, D_k, is a residual defined by: $D_k + \omega_{kj}[X_j - X^{\circ}_j] = \omega_{kj}X_j - \omega^{\circ}_{kj}X^{\circ}_j$, that is, the "output" and "distributive" effects sum exactly to the observed change in income. In aggregate, the "downstream" income increase was almost two-thirds the magnitude of the direct one, and it accrued overwhelmingly to nonfarm households. The nonzero distributive effect in aggregate arose from the fact that the actual 1974 paddy technology was more intensive in its use of intermediate inputs and migrant labor than its hypothetical counterpart, so that the sum of the income parameters $\{\omega_{k5}\}$ was smaller in the presence of the project.

To complete the picture, let us now look at the "autonomous" changes between 1967 and 1974, $(\mathbf{Z}^{\circ}_{1974} - \mathbf{Z}^{\circ}_{1967})$.[5] In the absence of the

[5] The gross output estimates for 1967 in the absence of the project are not reported in table 3. They differ only from their 1967 with project counterparts in that total gross output is 11% less at $480.7 million, the bulk of the discrepancy being in sectors 13, 14, 15, 21, 26, and 34.

project, regional gross output would have increased by about 30%, and value added and household incomes by about 35%. The principal source of autonomous expansion was the increase in government outlays on both current and capital accounts, the former rising over 80% and the latter, which were far smaller, by about 50%. Excluding the agricultural complex, the output of the remaining sectors is demand-driven, so that a failure to undertake the project coupled with static government expenditures under other headings would have resulted in regional production and incomes growing at only half their actual pace over the period. Even so, the autonomous growth pattern would not have been an equitable one. As table 4 makes plain, the principal beneficiaries would have been nonfarm households, whose incomes are well above the regional average. Similarly, the incomes of nonproject farm households would have been buoyed by rising rubber output; but the rises in the incomes of paddy farm households over their 1967 levels would have been of the order of 10%.

Balancing Investments

To complete this analysis of the project's impact on the region, it is necessary to form some estimate of the investment needed to realize the "downstream" effects. At one extreme it could be assumed that all sectors other than that producing paddy were suffering from excess capacity to such an extent that no additional investment was needed to complement the project itself. But this is hardly realistic in the light of the investments in buildings, housing, vehicles, and rice milling which accompanied the surge in incomes after 1970. Unfortunately, the available data provide only a sketchy investment series for the period in question, so the following estimates of investments related to "downstream" effects are inevitably somewhat tentative.

For present purposes, the relevant investment deliveries were made by sectors 14, 26, 27, and imports. An estimate of the investment needed to realize both "autonomous" and "downstream" increases in regional value added is obtained by omitting construction deliveries to the Muda project. Without discounting, this investment reached a cumulative total of $240 million in 1972 prices. Leaving aside additional investments in the rice-milling sectors, which took the form mainly of extra drying capacity to handle a second crop and did not exceed $5 million (FAO/IBRD), it seems plausible that the composition of the investments needed to support "autonomous" growth and "downstream" effects would not be so very different. Now the "autonomous" increase in value added between 1967 and 1974 was $110.4 million, while the "downstream" value added attributable to the project at maturity in 1974 was $50.5 million. Apportioning the $240 million additional investment in the same ratio as that for value added, we arrive at an estimate of $75 million for the cumulative, undiscounted total investment associated with the steady state "downstream" increase in value added.

This estimate is, however, almost certainly on the high side; for much of residential and nonresidential construction was undertaken by the state or federal governments. Moreover, it is unlikely that extra investments were made much in advance of the appearance of the project's "downstream" effects in 1970. Fragmentary evidence suggests that annual private investment in housing and other buildings would have been about $7 million lower in the absence of the project from 1970 onward. Cumulated over four years, this approach yields an estimate of "downstream"-related investments of $38 million. Taking the two estimates together, it seems fairly probable that realizing each dollar of "downstream" value added associated with the project needed between $0.75 and $1.5 of complementary investment appropriately distributed over all other sectors.

Conclusions

It must be emphasized that the frailties of the data base, and the many assumptions thus entailed in deriving results, demand some caution in drawing conclusions from the empirical analysis. Nevertheless, the broad orders of magnitude of certain key variables should be sufficiently solid to warrant some confidence in our main findings. In aggregate, the Muda project's downstream effects were of the same order as its direct effects: for every additional dollar of value added in paddy production generated by the project at maturity, about 75¢ of value added were generated by downstream effects. Also, each dollar of downstream value added probably was supported by just over a dollar of additional investment in plant and

equipment spread appropriately over the sectors which expanded in response to the project. The direct effects of the project did not worsen the distribution of income among farm households, but its downstream added value accrued mainly to the nonfarm households engaged in paddy milling and the production of nontradables. Although the spread in nonfarm incomes was wide, the lion's share of downstream income went almost certainly to households which were better-off than those engaged in paddy farming. Thus, while the project's downstream effects did much to boost the aggregate income of this relatively poor region, they worsened the intraregional distribution of income. Last, it is clear that, "new technology" notwithstanding, the project's production linkages were much weaker than its consumption linkages, for value added in paddy production accounted for more than 80% of gross output. Hence, even allowing for the expansion of paddy milling and agricultural machinery services, the doubling of paddy output injected into the system far more final demand from rising farm incomes than demand for intermediates (with final demand exogenously fixed). While there can be no claim that these findings are typical for all investment projects in LDCs, we believe that they provide a plausible first stab at the parameters for peasant agriculture, at least.

Price Endogenous Mathematical Programming As a Tool for Sector Analysis

Bruce A. McCarl and Thomas H. Spreen

The question, "Why use a mathematical programming model at the sectoral level?" is addressed. To address this question, discussion is presented mathematically and verbally upon mathematical programming sector models in which both price and quantity are endogenous variables. The discussion covers both the theoretical properties and the empirical concerns which must be faced in applying such models. Discussion is also presented upon the usefulness of the modeling approach for policy analysis. Selected bibliograpic citations' use of the approach in policy analysis are given.

Key words: mathematical programming, policy analysis, sector modeling.

Economists and agricultural economists long have been interested in the use of models as an input to planning and prediction within an economy. This interest has focused with particular intensity upon determining the direct and indirect impacts of alternative policies.

Various methodologies have been utilized to formulate these models. In studies in which the entire economy and, particularly, linkages between sectors are of interest, input-output analysis has been used. In other studies where the objective has involved identification of a sector's structure, various econometric approaches have been taken. To simulate the effect of new policies upon a sector, however, mathematical programming has proven to be a particularly useful tool (Blitzer, Clark, and Taylor review the various approaches).

Large-scale, price-exogenous, linear programming models have been used extensively by agricultural economists to simulate the impact of farm programs upon the agricultural sector (as in the work presented in Heady and Srivistava). These large-scale linear programming models have included the restrictive assumption of fixed market prices or quantities (Heady and Srivistava, p. 420), thereby ignoring the interrelationships of aggregate price and quantity. Sector analyses which recognize price-quantity interrelationships may be treated as spatial and/or intertemporal equilibrium problems. Samuelson (1952) first showed how the problem of partial equilibrium within spatially separated markets could be solved through mathematical programming. Takayama and Judge (1964a, b), using linear, price-dependent, demand and supply functions, extended the Samuelson formulation so that the spatial structure of prices, production, factor use, and consumption were determined with quadratic programming.

Quadratic programming formulations have been used extensively (e.g., Judge and Takayama, Hall et al.). Duloy and Norton (1975), through the use of separable programming, have approximated the quadratic objective function as a linear function enabling the simplex method to be utilized for solution, thereby expanding the size and scope of problems which can be considered.

Despite its widespread use, the arguments for and process of using a mathematical programming sector model are unclear to many. The nature of the objective function in the quadratic programming model, for example, is frequently misunderstood. The objectives of this paper are threefold. First, the paper will present the microeconomic foundations of mathematical programming sector models and the embodied theoretical aggregation processes. Following this, the specification of

such models is reviewed and discussed and, finally, discussion and a review are presented on the possibilities the formulation provides for policy analysis.

Microeconomic Background and Aggregation

A mathematical programming sector model typically contains activities which represent production and consumption of outputs. In the following sections we first discuss the behavior of an individual producer. Next, a procedure for aggregating individual producers is presented and the behavioral characteristics of aggregate production are discussed. Finally, this is related to the formulation of a quadratic programming sector model.

The Individual Producer

In economic analysis a sector is usually assumed to be made up of a large number of participants, each of whom seeks to optimize some objective. Thus, it is appropriate first to examine the actions of the economic entities comprising the sector of interest. We shall assume that producers and consumers operate in competitive markets for both factors and outputs. The producers produce some number of homogenous outputs and compete for the same factors of production. Assume each producer has a finite set of production processes with each representing a particular way of combining a maximum of n-owned factors with a maximum of m-purchased factors to bring one unit into production. Each production process is assumed to be technically efficient. The producer is assumed to maximize profit in choosing these production processes.

To develop mathematically the producer model (Naylor), define q_k to be level of the kth production process, $k = 1, \ldots, p$. Furthermore, define:

X_{ik} as the use of the ith purchased factor in the kth production process ($i = 1, \ldots, m$; $k = 1, \ldots, p$),

Y_{jk} as the use of the jth owned factor in the kth production process ($j = 1, \ldots, n$; $k = 1, \ldots, p$),

Z_{hk} as the yield of the hth output from the kth production process ($h = 1, \ldots, S$; $k = 1, \ldots, p$),

Y_j as the quantity of the jth owned factor available to the producer ($j = 1, \ldots, n$),

P_h as the market price per unit of the hth output ($h = 1, \ldots, S$),

r_i as the market price per unit of the ith purchased factor ($i = 1, \ldots, m$), and the following conversion coefficients: a_{ik} as the quantity of the ith purchased factor required by one unit of the kth production process ($i = 1, \ldots, m$; $k = 1, \ldots, p$), b_{jk} as the quantity of the jth owned factor required by one unit of the kth production process ($j = 1, \ldots n$; $k = 1, \ldots, p$), c_{hk} as the quantity of the hth output yielded by one unit of the kth production process ($h = 1, \ldots, S$; $k = 1, \ldots, p$).

Assuming constant returns to scale, the producer's profit function can be written as

$$\Pi = \sum_{k=1}^{p} \left(\sum_{h=1}^{S} p_h Z_{hk} - \sum_{i=1}^{m} r_i X_{ik} \right).$$

From the definitions, the following constraints occur:

$$(1) \quad -X_{ik} + a_{ik} q_k = 0 \quad (i = 1, \ldots, m;\ k = 1, \ldots, p),$$

$$(2) \quad -Y_{jk} + b_{jk} q_k = 0 \quad (j = 1, \ldots, n;\ k = 1, \ldots, p),$$

$$(3) \quad Z_{hk} - c_{hk} q_k = 0 \quad (h = 1, \ldots, S;\ k = 1, \ldots, p), \text{ and}$$

$$(4) \quad \sum_{k=1}^{p} Y_{jk} \leq Y_j \quad (j = 1, \ldots, n).$$

Thus, the producer's problem may be formulated as the following linear programming problem:

Max Π,
subject to (1)–(4) above, and

$$q_k, X_{ik}, Y_{jk}, Z_{hk}, \geq 0 \quad (i = 1, \ldots, m;\ j = 1, \ldots, n;\ h = 1, \ldots, S;\ k = 1, \ldots, p).$$

Given the values for all necessary parameters and prices, the problem can be solved easily via linear programming. It will be more instructive, however, to formulate the Lagrangian for this problem.

Let L denote the Lagrangian

$$L = \Pi + \sum_{j=1}^{n} \lambda_j \left(Y_j - \sum_{k=1}^{p} Y_{jk} \right) + \sum_{i=1}^{m} \sum_{k=1}^{p} \nu_{ik} \, (X_{ik} - a_{ik} q_k) + \sum_{j=1}^{n} \sum_{k=1}^{p} \omega_{jk} \, (Y_{jk} - b_{ik} q_k)$$

$$+ \sum_{h=1}^{S} \sum_{k=1}^{p} \sigma_{hk} \, (-Z_{hk} + c_{hk}q_k).$$

Kuhn-Tucker conditions provide the necessary and sufficient conditions for a constrained maximum at q°_k, X°_{ik}, Y°_{jk}, Z°_{hk}, λ°_j, ν°_{ik}, σ°_{hk}, ω°_{jk}. Mathematically, the conditions for this problem are as follows.

Production Activities:

$$\text{(5a)} \quad \frac{\partial L}{\partial q_k} = - \sum_{i=1}^{m} \nu^\circ_{ik} a_{ik} - \sum_{j=1}^{n} \omega^\circ_{jk} b_{jk} + \sum_{h=1}^{S} \sigma^\circ_{hk} c_{hk} \leq 0 \quad (k = 1, 2, \ldots, p),$$

$$\text{(5b)} \quad \frac{\partial L}{\partial q_k} q^\circ_k = 0 \qquad (k = 1, 2, \ldots, p),$$

$$\text{(5c)} \quad q^\circ_k \geq 0 \qquad (k = 1, 2, \ldots, p);$$

Purchased Factors:

$$\text{(6a)} \quad \frac{\partial L}{\partial X_{ik}} = -r_i + \nu^\circ_{ik} \leq 0 \quad (i = 1, 2, \ldots, m;\ k = 1, 2, \ldots, p),$$

$$\text{(6b)} \quad \frac{\partial L}{\partial X_{ik}} X^\circ_{ik} = 0 \quad (i = 1, 2, \ldots, m;\ k = 1, 2, \ldots, p),$$

$$\text{(6c)} \quad X^\circ_{ik} \geq 0 \quad (i = 1, 2, \ldots, m;\ k = 1, 2, \ldots, p);$$

Owned Factors:

$$\text{(7a)} \quad \frac{\partial L}{\partial Y_{jk}} = -\lambda^\circ_j + \omega_{jk} \leq 0 \quad (j = 1, 2, \ldots, n;\ k = 1, 2, \ldots, p),$$

$$\text{(7b)} \quad \frac{\partial L}{\partial Y_{jk}} Y^\circ_{jk} = 0 \quad (j = 1, 2, \ldots, n;\ k = 1, 2, \ldots, p),$$

$$\text{(7c)} \quad Y^\circ_{jk} \geq 0 \quad (j = 1, 2, \ldots, n;\ k = 1, 2, \ldots, p),$$

Outputs:

$$\text{(8a)} \quad \frac{\partial L}{\partial Z_{hk}} = P_h - \sigma^\circ_{hk} \leq 0 \quad (h = 1, 2, \ldots, S;\ k = 1, 2, \ldots, p),$$

$$\text{(8b)} \quad \frac{\partial L}{\partial Z_{hk}} Z^\circ_{hk} = 0 \quad (h = 1, 2, \ldots, S;\ k = 1, 2, \ldots, p), \text{ and}$$

$$\text{(8c)} \quad Z^\circ_{hk} \geq 0^1 \quad (h = 1, 2, \ldots, S;\ k = 1, 2, \ldots, p).$$

If output h is produced under the kth production process ($Z^\circ_{hk} > 0$), equation (8a) will hold with strict equality; thus, P_h equals σ°_{hk}. Substituting for σ°_{hk} in equation (5a) and rearranging gives

$$\text{(9)} \quad \sum_{h=1}^{S} p_h c_{hk} \leq \sum_{i=1}^{m} \nu^\circ_{ik} \, a_{ik} + \sum_{j=1}^{n} \omega^\circ_{jk} b_{jk} \qquad (k = 1, \ldots, p).$$

The sum on the left-hand side of equation (9) represents the return to the producer from one unit of production of the kth production process (the price of the hth output times the quantity produced from one unit of the kth production process). The Lagrangian multipliers ν°_{ik} and ω°_{jk} are the prices imputed to the purchased and owned factors of production. Therefore, the right-hand term represents the imputed resource cost of producing one unit with the kth production process. Then (9) says that the total return from one unit produced under the kth production process must be less than or equal to the total imputed costs from one unit produced under the kth production process. This fairly technical explanation can be interpreted loosely as the well-known marginal condition for profit maximization: continue to supply a product up to the point where price equals marginal cost.

Rewriting (5a) gives

$$\text{(10)} \qquad r_i \geq \nu^\circ_{ik}.$$

Above we noted that ν°_{ik} is the imputed cost of the ith purchased factor used in the kth production process. Equivalently, ν°_{ik} is the imputed marginal value given to the ith purchased factor in the kth production process. Thus, (10) is analogous to the familiar marginal condition: continue to apply a variable factor up to the point where its price equals the value of its marginal product.

Rewriting (7a) gives

$$\text{(11)} \qquad \omega^\circ_{jk} \leq \lambda^\circ_j,$$

where ω°_{jk} is the marginal value imputed to jth owned factor used in the kth production process. λ°_j is the marginal value imputed to the availability of the jth owned factor. Thus, (11) implicitly states that the marginal value of the jth owned factor used in the kth process must

[1] These are not all of the Kuhn-Tucker conditions. The others insure that (a) all constraints are satisfied, (b) all shadow prices are nonnegative, and (c) complementary slackness holds. These conditions have been omitted to shorten the discussion.

be less than or equal to the marginal value imputed to the jth owned factor.

The Aggregate

The above marginal conditions give the rules by which producers make production decisions. Within the competitive framework, individual producers cannot affect factor or product prices. As we direct our attention to the aggregate, the assumption of exogenously determined prices for all factors and outputs is no longer tenable. When producers of a sector are significant consumers of a factor or suppliers of a product, the interrelationship of price and quantity needs to be considered. Assume that the inverse demand relation for the output of the sector exists and is given by

$$(12)\quad P_h = f_h\,(\mathbf{Z}, \Theta), \qquad (h = 1, \ldots, S),$$

where Θ is a vector of exogenous factors and $\mathbf{Z}$ is a mxl vector with elements equaling each commodity's total sector output production.

Further, assume the inverse supply relation for purchased factors to the sector exists and is given by

$$(13)\quad r_i = g_i\,(\mathbf{X}, \Gamma), \qquad (i = 1, \ldots, m),$$

where Γ is a vector of exogenous factors and $\mathbf{X}$ is an mxl vector of total sectoral use of purchased factors.

We may now state the underlying premise for the aggregate model. The production level of each activity should be determined by the first order conditions with which an individual producer will select his production level. Additionally, demand and supply relations should be included. This leads to an aggregate model wherein participants individually behave as small competitive units, yet collectively, price and quantity are endogenous. Therefore, we will now construct conditions that reflect this premise and then develop an optimization model that yields these conditions. This requires a redefinition of variables to include the producer dimension. Let q_{lk} be the level of the kth production process utilized by the lth producer ($l = 1 \ldots, L$; $k = 1, \ldots, p$). Similarly define X_{ilk}, Y_{jlk}, Z_{hlk}, a_{ilk}, b_{jlk}, c_{hlk}. Using these definitions, it follows that the sectoral use of the ith purchased factor and the sectoral supply of the hth output are

$$(14)\quad X_i = \sum_{k=1}^{p} \sum_{l=1}^{L} X_{ilk} \qquad (i = 1, \ldots, m),$$

$$(15)\quad Z_h = \sum_{k=1}^{p} \sum_{l=1}^{L} Z_{hlk} \qquad (h = 1, \ldots, S).$$

We will maintain the assumption that owned factors of production belong to the individual producers, thus Y_{jl} is the endowment of owned factor j to producer l ($j = 1, \ldots, n$; $l = 1, \ldots, L$).

The aggregate conditions will be constructed from the above microconditions. First, rather than output price being a constant, it is now given by the functional relation (12). Assuming a vector of optimal levels of output ($\mathbf{Z}^\circ$), we can now develop an aggregate equation relating price to imputed value analogous to (8a) where $\sigma^\circ{}_h$ is the dual variable from (15).

$$(16)\quad F_h\,(\mathbf{Z}^\circ, \Theta) - \sigma^\circ{}_h \le 0 \qquad (h = 1, \ldots, S).$$

Similarly, an analogous condition to (10), where $\nu^\circ{}_i$ is the dual variable associated with (14), is

$$(17)\quad g_i\,(\mathbf{X}^\circ, \Gamma) \ge \nu^\circ{}_i \qquad (i = 1, \ldots, m).$$

Furthermore, individual producers are price takers equating aggregate price with the price they receive (pay) when they produce an output (consume a factor). The imputed marginal cost at which a producer is willing to sell output is greater than or equal to the aggregate price and the producers imputed value of a factor is less than or equal to its aggregate price. Thus, conditions relating aggregate and microprices need to be imposed:

$$(18)\quad \sigma^\circ{}_h \le \sigma^\circ{}_{hlk} \quad (h = 1, \ldots, S,\ l = 1, \ldots, L,\ K = 1, \ldots, p),$$

$$(19)\quad \nu^\circ{}_i \ge \nu^\circ{}_{ilk} \quad (i = 1, \ldots, m,\ l = 1, \ldots, L,\ K = 1, \ldots, p).$$

Complementary slackness-type conditions also are present for (16)–(19), considering cases where production or factor use is zero.

Assuming that both supply and demand functions are linear, define the demand and supply curves as

$$(20)\quad P_h = G_h - \mathbf{H}_h\,\mathbf{Z} \quad (h = 1, \ldots, S), \text{ and}$$

$$(21)\quad r_i = E_i + \mathbf{F}_i\,\mathbf{X} \qquad (i = 1, \ldots, m),$$

where G_h and E_i are scalers and $\mathbf{H}_h$ and $\mathbf{F}_i$ are row vectors.

Given these definitions, we now follow a procedure suggested by Samuelson (1947) who states: "In some cases . . . it is possible

to formulate conditions of equilibrium as those of an extremum problem" (p. 23). The following optimization model possesses the first-order conditions which are developed above, based upon the aggregation process. Actually, this step requires two assumptions: (*a*) the demand and supply functions must be integrable, and (*b*) the demand and supply functions must be independent of sector activity, i.e., the model must be partial equilibrium. Both of these assumptions will be discussed later.

$$(22)\quad \text{Max } \mathbf{Z}'\mathbf{G} - 1/2\mathbf{Z}'H\mathbf{Z} - \mathbf{X}\,\mathbf{E}' - 1/2\mathbf{X}'F\mathbf{X},$$

subject to

$$-X_{ilk} + a_{ilk}\, q_{lk} = 0 \quad (i = 1, \ldots, m;\ l = 1, \ldots, L;\ k = 1, \ldots, p),$$

$$-Y_{jlk} + b_{jlk}\, q_{lk} = 0 \quad (h = 1, \ldots, S;\ l = 1, \ldots, L;\ k = 1, \ldots, p),$$

$$Z_{hlk} - c_{hlk}\, q_{lk} = 0 \quad (h = 1, \ldots, S;\ l = 1, \ldots, L;\ k = 1, \ldots, p),$$

$$\sum_{l=1}^{L} \sum_{k=1}^{p} X_{ilk} - X_i = 0 \qquad (i = 1, \ldots, m),$$

$$-\sum_{l=1}^{L} \sum_{k=1}^{p} Z_{hlk} + Z_h = 0 \qquad (h = 1, \ldots, S),$$

$$\sum_{k=1}^{p} Y_{jlk} \leq Y_{jl} \quad (j = 1, \ldots, n;\ l = 1, \ldots, L), \text{ and}$$

$$X_{ilk},\ Y_{jlk},\ Z_{hlk},\ q_{lk} \geq 0 \qquad \text{for all } i, j, k, l.$$

In the first order conditions of this problem, the micro dual variables must take on subscripts denoting producers (ν_{ilk}, ω_{jlk}, σ_{hlj}), and new dual variables are introduced associated with equations (14) and (15). The reader, however, can easily verify that by assuming good h is produced ($Z_h > 0$), that the dual variable from (14) equals the product price from the demand curve, and by further assuming that the microunit produces ($Z_{hlk} > 0$), then the equation of price and marginal cost follows as discussed above. Similar arguments could be made for factors. Thus, the formulation implies the microeconomic conditions for production by competitive firms are met.

The objective function no longer represents producer profit. The substitution of price-dependent, product-demand, and factor supply schedules transforms the objective function into a measure of consumer's plus producer's surplus. Consumer's plus producer's surplus or net social benefit is defined as the area between the demand and supply curves to the left of their intersection (Samuelson 1952, Takayama and Judge 1971, p. 108).

The constrained optimization model takes as data production coefficients (a_{ilk}, b_{jlk}, c_{hlk}), availability of owned factors, demand schedules for outputs, and supply schedules for purchased factors. The solution of the model generates an equilibrium price and quantity of outputs, usage patterns for purchased and owned factors, prices of purchased factors, and imputed values of owned factors.

In the derivation of the model, it is assumed that the sector is composed of many competitive microunits, none of which can individually influence output or factor prices. Each producer supplies according to the rule: equate product price to marginal cost of producing one more unit of that product. Thus, the sectoral supply schedule is an "aggregate" marginal cost schedule. Similarly, each producer uses purchased factors according to the rule: equate factor price to marginal value product. Thus, the sectoral derived demand for purchased factors will be an aggregate marginal value product schedule. An important, although obvious point, is that the model does not require supply of outputs or demand for factor schedules. Rather, these schedules are derived or projected internally based upon production possibilities, output demand, and factor supply.

The artificial nature of the objective function must be emphasized. As Samuelson (1952, p. 288) stated: "This magnitude (the objective function) is artificial in the sense that no competitor in the market will be aware of or concerned with it. It is artificial in the sense that after an 'Invisible Hand' has led us to its maximization, we need not necessarily attach any social welfare significance to the result. . . ." Hence, the solution of the quadratic programming problem can be characterized as a simulation of industry behavior under the assumption of competition.

The competitive behavior simulating properties of the model provides a potentially powerful tool for policy makers. Excepting the case of centrally planned economies, the government cannot dictate production patterns that are consistent with its objectives. Thus, through its formulation the model explicitly

recognizes the difference and potential conflict between governmental and producer objectives. The model allows the policy analyst to specify a change designed to meet some governmental objective, and then observe simulated sectoral response to the policy change. The model does not assume that sectoral participants will respond to the government "wants"; rather, each producer optimally adjusts so as to maximize profits. Furthermore, producer adjustment is endogenous to the model.

A Digression on Assumptions

In order to formulate the mathematical programming model at the aggregate level, it was necessary to assume integrability of product demand and factor supply functions and a partial equilibrium setting. The purpose of this section is to offer discussion of these assumptions and point out ways of relaxing them in formulations.

Integrability refers to conditions in which the matrix of first derivatives of the factor supply and product demand functions must be symmetric (Hurwicz and Uzana). This implies that the cross-price effects are equal over all commodity pairs. The implications of this requirement vary depending upon whether one is dealing with supply or demand. Following Zusman, "in the case of supply functions the classical assumptions of the theory of production, in fact, yield the symmetry conditions" (p. 55). However, in the case of demand functions, an individual function (of which the mathematical programming functions are aggregates) "consists of a symmetric substitution term and an income effect term" (p. 55). Thus the cross-price effects need not be symmetric. The assumption of integrability requires symmetric cross-prices effects which implies that the effect of income on consumption is identical across all commodities of interest or zero. A commonly made statement regarding integrability is—so what, even if the quadratic matrix is not symmetric, a symmetric quadratic matrix can be formed which when pre- and post-multiplied by a vector will yield the same produce as gotten when multiplying with the asymmetric matrix. This would be done by averaging the cross-product terms and entering them in the off-diagonal positions. This definitely yields the same product. However, when this approach is followed, the derivatives are altered and the equation of price and marginal cost is no longer a first-order condition. Thus this manipulation, while numerically correct, removes the economic meaning underlying the model.

Models that do not require the integrability assumption can be formulated by incorporating price and quantity variables into the primal formulation (Plessner and Heady). Thus, both price and quantity equilibrium conditions are imposed on the primal formulation, as contrasted with the specification of (22) in which quantity equilibrium conditions are present only in the primal, and price equilibrium conditions are generated as Kuhn-Tucker conditions. In the nonintegrable approach, if factor supply and product demand functions are linear, the formulation can be treated as a linear complementarity programming problem (Takayama and Judge 1971, Stoecker, Polito). The objective function of the nonintegrable formulation no longer represents the area between the aggregate production supply and demand functions or net social welfare. For further discussion, see Takayama and Judge (1971).

The partial equilibrium assumption arises because the formulation does not incorporate the income generated by the sector as a simultaneous shifter of the model's product demand function. If the modeled sector is small relative to the entire economy, this should not be a serious problem. If a major sector or set of sectors is of interest, however, the income generated within that sector may have a major impact on aggregate consumer demand. A formulation which does not require the partial equilibrium assumption has been developed by Yaron, who specified a lagged relationship in which aggregate consumer demand in the current period is a function of aggregate consumer income in the previous period. Norton and Scandizzo relayed this assumption in a simultaneous fashion, developing a general equilibrium model in which demand is rotated as a function of current income. Integrability is also a consequence of the Norton and Scandizzo formulation as an income shifter is explicitly introduced, leaving only the symmetric substitution terms.

Specification of Mathematical Programming Sector Models

The preceding discussion has emphasized the economic logic underlying price endogenous

mathematical programming sector models. In order to apply sector modeling, however, one obviously has to specify activities, constraints, etc. In doing this, certain issues need to be faced concerning empirical specification, dynamics, embodied economic behavior, validation, and computation. We now proceed to discuss these issues. Given the review objective of this paper, the discussion will contain many references to examples of the ways these issues have been handled.

Empirical Specification

The theoretical model developed above explicitly aggregates individual producers. In nearly all empirical work, however, the specification to include every individual producer is an impossible task. To simplify this task, empirical studies have attempted to identify homogenous groups or producers. Each group is then treated as an individual producer. While this approach greatly reduces model size, the aggregation of individuals into homogenous groups introduces aggregation bias. Previous authors have sought conditions under which this "preliminary" aggregation may be done to eliminate or minimize aggregation bias. Theoretical zero aggregation bias explorations include Day 1963a, Miller 1966, Paris and Rausser, and Spreen and Takayama. The conditions proposed by these authors, however, are highly restrictive and have led to other studies which have proposed practical methods to minimize aggregation bias. Sheehy and McAlexander propose that firms should be classified on the basis of the most limiting resource for each product. In an example, they show that use of this classification leads to less aggregation bias than procedures based simply on size and type of firm. Their results are supported by Frick and Andrews. Buckwell and Hazell extend this procedure to multiperiod models. A related paper by Hazell shows how the Buckwell and Hazell criteria were used in the construction of a sector model.

Aggregation questions are not limited only to the grouping of producers. Frequently sector models will have regions in which producers share common resources (e.g., hired labor and land). Regions are most frequently selected because of a mixture of climatological and geographic considerations. Egbert and Kim provide a study that examines errors in aggregation due to spatial specification.

Once a level of aggregation has been chosen, data must be developed. The production possibilities set is the heart of most of the mathematical programming sector models. Data requirements for this set are rather imposing and its development is probably the most time-consuming part of the research effort. These coefficients are formed, most frequently, from averaged farm data obtained via farm surveys or census data in conjunction with primary data collection (for example, see Bassoco and Rendon, Eyvindson). However, several other approaches are possible. First, data may be generated from purely secondary sources (Baumes, Candler 1977), or alternatively, detailed surveys may be designed to yield usable data (Kutcher and Scandizzo 1976b). Data for production also have been formed based upon aggregate data using an approach which attempts to recreate equilibrium (Miller 1978, Fajardo), much like the approach used in input-output analysis.

In addition to data on production, supporting data on factor supply and product demand are required. Product demand schedules typically are obtained through econometric estimation. Demand curve estimates have been made using both own-price elasticities and income elasticities. The income elasticities have been transformed using the Frisch methodology (Frisch, Cappi et al.). Brandt and Goodwin recently have found fault with this procedure. These schedules usually specify price as a function of own quantity only. Duloy and Norton (1975) discuss a formulation in which demand price depends upon more than one commodity. Substitution also is modeled when the demand functions contain off-diagonal terms. The form of product demand curves is most frequently linear, although constant elasticity curves have been incorporated using separable programming techniques (Rodriguez). These linear curves are formed directly by estimation or by taking the elasticity and a known price quantity point, then forming a tangent linear curve.

Factor supply schedules are more difficult to obtain. Land and labor supply schedules in agricultural models are particularly difficult to estimate. Little econometric work has been done to assist in generating these schedules, and, thus, many researchers have assumed perfectly elastic factor supply schedules at the prevailing market price. This assumption may result in the model's output supply schedule being more elastic than the actual supply

schedule. Other approaches include supply curve construction using an assumed elasticity (e.g., Fajardo's land market) or the use of linear programming constraints (e.g., Duloy and Norton's 1973 labor market). When using linear programming constraints for the specification of the supply curve, an important topic that arises is the specification of the minimum value of a resource. Linear programming will either completely use up a resource or drive the value to zero. In a practical sense, resources may have a minimum value in other enterprises or will just not be available for less than a minimum return. Duloy and Norton (1973) specify a reservation wage in the labor market and experiment with alternative numerical specifications.

Another problem faced in specification of factor supply and product demand schedule is the difficulty faced when trying to define a particular market. Due to informal markets and the multitude of market channels, it is often difficult to delineate relevant markets. This problem may be exacerbated as the focus of the modeling effort moves from the farm to the region to the sector, etc. (Kutcher discusses the formation of regional demand curves.)

Dynamic Specification

The development of the time frame to be used in the model can be difficult. Most agricultural applications of this modeling technique have covered annual crops and have thus developed a one-year static equilibrium-type model. However, when dealing with either livestock or perennial crops, the need exists to deal with multiyear consequences. This has been accomplished in three ways. First, average farm budgets have been used (Eyvindson). Second, the system has been assumed to repeat itself at the same level, and multiple year physical budgets have been averaged back to a single year (as suggested by Throsby and done in Brandao). Third, the long-run planning horizon has been partitioned into two parts. These formulations begin with an initial inventory, and a finite number of years is simulated. The inventory at the end of the explicit simulation is valued to reflect expected future returns; discounting and time preference of money also must be considered. Dean and Benedictus have used this approach for a long explicit planning horizon; Spreen, McCarl, and White; and White et al., have used it for shorter explicit horizons. Spreen, McCarl, and White also introduce a demand curve for ending inventory.

When the dynamics of the modeled sector are considered, one must distinguish between complete adjustment and partial adjustment to changes in product prices, factor prices, new technology, etc. Many applications have used supply equations which allow equilibrium adjustment of supply to demand. The dynamic setting generally assumed is in some sense long-run equilibrium (although investment is not generally endogenous). Bassoco and Norton call the dynamic setting short-run equilibrium. Short-run supply equations have been used in some spatial equilibrium studies (Kottke). An alternative approach is the use of a recursive formulation (Day 1963b). The recursive model recognizes that the production process for some commodities is long-term, and thus only partial adjustment can be achieved in the short-run. However, as new price information is received, producers may revise their long-term plans. Thus a recursive programming-model solution may represent the results of a series of plans each in operation for one time period (Spreen, McCarl, White). Another variation of a recursive formation is to employ so-called flexibility constraints to constrain allowable acreages of certain crops (Schaller, Day 1963b). Sahi and Craddock review estimation techniques for the use of flexibility constraints.

Behavioral Specification

Behavioral response to price changes is not always satisfactorily modeled by the competitive behavior assumed above (we will not discuss centrally planned economies; see Kornai). Takayama and Judge (1971), and Duloy and Norton (1979) have both presented formulations in which monopolistic or monopsonistic forms of competition have been assumed. Louwes, Boot, and Wage, and Guise and Aggrey-Mensah provide examples where forms of monopolistic competition have been used. Allen (pp. 200–4) provides examples on how to derive reaction functions for situations in between competitive and monopolistic. These functions could then be used in formulating a model.

Risk and the incorporation of risk aversion is another major behavioral feature which may be included in a sector model. Hazell and

Scandizzo (1974, 1977) have written on this topic and have developed a linear programming approach in which they include risk as an additional cost of production. However, they note that "there are definite problems . . . for exact aggregation . . ." (Hazell and Scandizzo 1974, p. 240), and state that the risk-aversion characteristics must be "suitable averages" (Hazell and Scandizzo 1977, p. 206) of individual risk-aversion characteristics. Thus, the development of the aggregation principles under risk has not yet been fully explored.

Using Hazell and Scandizzo's assumptions, several authors have included risk in sectoral formulations. Basic data needs include a historical time series on gross returns to crops. The underlying assertion is that farmers consider this variability in making acreage decisions. Hazell et al. argue that the descriptive performance of models can be improved considerably by introducing risk-averse behavior, and that biases introduced by ignoring risk can be quite significant. Sectoral work by Simmons and Pomareda; Nieuwoudt, Bullock, and Mathia; and Rodriguez all support these statements.

Risk aversion has been included in microeconomic models via many alternative approaches (Anderson, Hardacker, and Dillon overview this literature). Several of the microapproaches are possible for aggregate specifications. Wicks reviews the general area of aggregate risk specifications.

A final issue involving the behavioral specification of these models concerns the presence of tenancy-type relationships. The incorporation of tenancy-type relations is potentially difficult as various forms of relationships lead to different resource allocations (D. Gale Johnson). Land tenure considerations generally have been ignored in mathematical programming sector models (or the assumption has been made that the owner and tenant operate jointly to maximize farm profits). Several linear programming analyses have been made on the question (e.g., Kutcher and Scandizzo 1976a, and Brandao). Cline also has explored the more aggregate consequences. However, with regard to mathematical programming sector models, this subject is apparently largely untouched. Reportedly Kutcher and Scandizzo (1976b) have done a sector model with consideration of sharecropping. The authors have not, however, examined reports on this research.

Validation

Given a fully specified model, one of the most difficult issues is the answer to the question: Well, now that the model is complete, do we have any confidence in the answers it gives? Validation or verification of these models has been examined by several researchers. Nugent began work on this topic in terms of checks as to whether the model's output corresponded to a known solution. Kutcher did further work validating both activity levels and the shadow prices. Rodriguez continued Kutcher's work. The basic validation tests which have been used involve (*a*) how well the model solution, when specified with base period data, corresponds to the real situation in that base period; (*b*) whether the model feasibly can produce the base period demand quantity; (*c*) how well the model replicates the base period quantity (a test of whether price equals marginal cost); and (*d*) how well the model replicates base period quantities with prices fixed at base period actuals. The validation tests which have been used generally relate to aggregate results. Regional production activities have not been validated systematically in the literature found by the authors. This is most likely because results from an aggregate model generally do not compare well to disaggregate regional production patterns. Linear programming models (and particularly ones which do not consider risk) tend to specialize at the submodel level.

A model which does not pass validation would most likely leave the researcher in a difficult position. These models are conditional normative by nature and are therefore frequently valid by assumption. Tests involving validation have been attempted but when a model is "invalid," the model is usually examined carefully in terms of adequacy of coefficients and/or structure. Usually changes are then made and the model is reexamined for validation (Candler 1979, provides an example of this).

Furthermore, validation of the aggregate results does not totally validate a model. One still must be concerned with the adequacy of the supply and demand curves. Given an equilibrium solution to a problem, the slopes of the curves may be varied quite widely (providing the curve continues to pass through the equilibrium points) and the same equilibrium produced. The supply and demand curves are generally implicitly assumed to be valid by

construct or valid through the process of their generation (i.e., econometric estimation).

The final issue on validation of linear programming models concerns their ability to predict what will happen in periods beyond their base specification. Shumway and associates (Shumway and Chang, Shumway and Talpaz) have investigated the ability of linear programming models for prediction. They conclude the technique to be a feasible method for estimation of the direct and cross elasticities of supply with approximately the same degree of accuracy as single equation econometric models.

Computation

The sheer size of these models can impose itself as an element in the formulation process. For example, Eyvindson, in his discussion of model shortcomings, states on several occasions that a shortcoming could be overcome by adding several hundred constraints. However, the linearization technique employed by Duloy and Norton (1975),[2] the new complementary pivot algorithms (see e.g., Stoecker), and the decomposition algorithms of Polito all provide approaches which allow (or potentially provide) the formulation and solution of much larger and more realistic problems.

Use of Mathematical Programming for Policy Analysis

The preceding discussion has emphasized the economic foundations and specification considerations involved when using mathematical programming sector models. Because of the explicit modeling of individual producer behavior, the technique is intuitively appealing. Even though groups of producers may employ a common set of factors to produce a relatively homogenous set of products, their production may vary implying differing response to governmental actions, availability of new technology, etc. The mathematical programming approach allows each production unit to adjust endogenously its output level and factor use to a change in the economic environment. Thus the power of the approach is revealed. Based upon a microeconomic data base, the response of producers to economic policy changes is simulated by the model. Further, the response to policy conditions which have not been imposed previously can be simulated. (Naturally, one runs the risk in this case that the model does not include the relevant adjustment parameters.) In summary, mathematical programming sector models can be valuable when used in a policy assessment setting. (The referenced policy document by the Mexican Government, Ministry of the Presidency, reinforces this statement.)

Model Specification for Policy Analysis

A principal feature of the modeling structure is its richness in terms of the ability to specify changes in the economic environment. Modifications may be incorporated through specification of new activities, new constraints, changes in right-hand-side values, and factor supply or product demand schedules, each of which will be dealt with briefly below.

New activities. To illustrate the addition of new activities, suppose some subset of firms in the sector is plagued with low levels of production (e.g., peasant farmers in a developing country). Alternative production activities may be specified for these firms which make use of new technology, better management practices, etc. (e.g., Spreen, McCarl, White). The modified model is solved and the analyst observes whether the newly specified activities supplant traditional production practices. Often production alternatives entail substitution of capital inputs for labor or more intensive use of purchased inputs such as fertilizers, improved varieties of seed, or veterinary services. Even though these alternatives result in increased output over traditional production techniques, they may not be profitable. Traditional techniques make extensive use of the peasant's cheapest input, labor; and the peasant's inability to acquire purchased inputs often result in traditional production techniques being more profitable to peasant farmers than "modern" alternatives. The mathematical programming approach allows the analyst to evaluate the system's effect of "modern" production alternatives versus traditional techniques. Thus, potential for adoption by producers and the projected effects on prices and quantities of foods and inputs may be judged. Caution also must be exercised in this situation because the data base from which a model is generated may

[2] Baumes and McCarl have investigated computational features of the Duloy and Norton linearization technique.

consist of farm budgets which reflect major obstacles to adoption, such as lack of infrastructure credit, etc. New technology activities, however, may not reflect these factors. Thus, the model may suggest adoption when it is not possible.

New constraints. Production quotas, export quotas, or restrictions on factor availability can be incorporated through the addition of new constraints (e.g., Taylor and Frohberg). For example, a restriction on aggregate production can be handled easily through specification of a constraint which restricts aggregate production of some commodity to a specified level. The model allows each firm to adjust individually and optimally to the production restriction. Here caution must be exercised regarding the nature of constraints. Linear programming finds the "best" solution within the constraints. Thus, if a constraint is imposed, the model will honor it. The model user must be careful to distinguish between enforceable constraints and "goals." An export quota is potentially enforceable while a minimum level of exports is a goal (producers ordinarily cannot be forced to export).

Right-hand-side changes. Changes in resource availability to the sector, such as land availability or transport capacity, can be incorporated through appropriate adjustments in right-hand-side values (e.g., Shei and Thompson). Suppose that some firms in the sector are geographically separated from consuming regions. The model allows specification of alternative or increased transport from the remote region. Thus, establishment of a new road could be simulated and its impact on aggregated production observed.

Factor supply and product demand modification. The imposition of price ceilings, minimum wage laws, increased taxes, or the introduction of imports can be incorporated through modifications of factor supply or product demand schedules (e.g., Simmons and Pomareda). This characteristic of the model allows one to simulate a wide array of policy instruments available to governments.

Policy Applications

Although the literature in this field has evolved relatively recently, the modeling framework has been used for a wide array of policy questions. The basic form of analysis has been comparative statics. Models generally have been validated for base periods, updated based upon projected shifts in supply and demand, then used to simulate response to and changes induced by policies. Supply response parameters also have been studied. The types of model usages reviewed here can be categorized broadly as foreign trade, commodity policy, input policy, project appraisal, and supply response exploration. A brief review of efforts in these areas is presented below. First, however, we will list briefly the major outputs which would be obtained from a model. For expository purposes, let us assume the model is multiregional, open to trade, containing crop and livestock activities. Given this type of structure, a model solution gives prices and quantities for both products and factors along with stock numbers at both the aggregate and regional levels. Further, the model would give functional and regional income distribution, export and import volumes, sectoral balance of trade, tariff revenues, subsidy expenses, interregional commodity movements, and welfare measures. Depending upon the analysis, other substantive items may be drawn from the model. Policy analysis with a model also creates indirect benefits such as an assessment team with sectoral perspective and a sectorally consistent data base.

Foreign trade. Analysis of foreign trade phenomena within a mathematical programming sectoral model has been done by several authors. The most obvious applications entail examination of a sector's reaction to changes in (*a*) export or import prices (Rodriguez and Fajardo have explored this), (*b*) trade volume restriction quotas (Simmons and Pomerada, Cappi et al., and Fajardo have explored this), and (*c*) changes in export levels (Meister, Chen, and Heady examine this). Less obvious foreign trade analyses include Duloy and Norton's (1973, 1979) explorations of comparative advantage—carried out by bounding exports and finding the shadow price on the export bound (which gives the difference between the export price and domestic cost of the product)—and Jabara's analysis of comparative advantage under risk and undistorted prices (e.g., using the shadow rate of exchange).

Commodity policy. Many research efforts have been carried out under the general topic of commodity policy. Representative of these efforts is the Meister, Chen, and Heady study of price supports or storage policy and Bassoco and Norton's study of price support pro-

grams. Such policies as commodity-specific controls or production subsidies (taxes) also may be simulated.

Input policy. Current environmental concerns have led to several sectoral studies in which quantities of factors like fertilizer have been limited (Taylor and Frohberg; Meister, Chen, Heady). Sensitivity to wage rate increases also has been examined (Simmons and Pomareda, Rodriguez).

Project appraisal. Mathematical programming sector models have been used by Hussain and Inman and Bassoco et al., to select projects which are viable at various rates of return. This has commonly been done in the project analysis literature (Little and Mirrlees). Use of the mathematical sector model, however, allows the effect of output price change (through the demand function) to be included.

Supply response termination. A major use of this class of models has been in deriving output supply response, input demand, factor substitution, and product-product possibilities. Response has been studied both with and without risk consideration. Howell and Bassoco and Norton employ sector models to derive output supply, factor substitution, and input demand relationships. These relations do not perfectly correspond to their theoretical analogues because the experiments (i.e., shifting the demand curve to derive output supply) are done by necessity in a multiproduct model and other things (prices, etc.) are not held constant. Further, due to the stepped nature of the functions arc elasticities are generally derived.

Other Applications

In an area with a literature as voluminous and as dynamic as that discussed herein, it is a major undertaking to reference the major pieces of work. The above sections have attempted to cover partially the literature. This section, however, is designed to add yet more references to the list.

Work in mathematical programming sector models has been extensive. Developing countries, in particular, have received attention. To mention a few, efforts have been done in Mexico (Goreux and Manne, Norton and Solis), Tunisia (Roe), Nicaragua (Fajardo), Northeast Brazil (Kutcher and Scandizzo 1976a, b), Philippines (Rodriguez), Zambia (Candler 1977), Guyana (White et al.), Central America (Cappi et al.), and Thailand (Stoecker, Heady, and Hoffman). Notable among these are the recent studies in Mexico which are summarized in a forthcoming book (Norton and Solis).

In the context of developed countries, a sampling of the research includes Canadian studies of the dairy (Sahi and Harrington) and the overall agricultural sector (Lattimore and Thompson). Work also has been done in England (Hazell), Portugal (Egbert and Kim), and Australia (Walker and Dillon). The U.S. also has received much attention with Heady and associates, in particular, contributing (Heady and Srivistava). Other studies include Miller 1978, Taylor and Frohberg, and Baumes.

In addition to the above citations, there are also several literature reviews and edited volumes which cover (or include) allied work. These include Manne; Neunteuful; Judge and Takayama; Kornai, Heady; Walker and Monypenny; Singh; and Blitzer, Clark, and Taylor.

Toward Optimum Policy

The use of these models for policy analysis and their richness in terms of ability to simulate policy has led many to wonder about the following question. Now, given the applicable set of policy instruments, can "optimum" policy be achieved? These thoughts lead either to misuse of models or to the formulation of difficult optimizing models. A classic example of misuse is one where a research team convinces itself that the country wishes to optimize nutritional production and then the research team replaces (or originally formulates) the objective function to do so. One needs only to wonder how many farmers will forego income to produce calories for the aggregate population to see the fault in this modeling strategy.

Alternatively, the problem can be formulated to maximize government objectives subject to the problem above, i.e., (20) being optimized. This type of formulation has been done by Candler and Norton, who call the area of investigation "multilevel programming." Attempts have been made to develop algorithms for its solution (Candler and Townsley; Fortuny and McCarl). However, these algorithms are rather cumbersome and demanding in terms of computer capacity. In-

formal iterative or search methods also may be used in the quest for optimum policy.

Notwithstanding the ways of finding optimum policy given an objective function, there is the problem of developing the objective function. Clearly, the determination of a unique quantity to maximize is difficult. This problem has been examined to some degree in the control theory area (Rausser and Freebairn). The need for an objective function can be somewhat finessed simply by tracing out the policy space by parametric solution of a model.

Obstacles to Use

The major difficulty with mathematical programming formulation is that its data requirements are extensive. Time, manpower, and financial resources required to construct a detailed model can be overwhelming. Certain authors, e.g., H. G. Johnson, have argued (justifiably, in the authors' opinion) that a highly qualified team is necessary to carry out this research. Available computer services also may be a major constraint. Other authors wonder, particularly in the developing country case, if the effort is an appropriate use of resources, e.g., Langham.

A subtle weakness of this type of model revolves around the institutional question of who will use it. The scope of such a model is quite frequently much wider than any group within a country. Beyond research use, then, there is the question of who will use such a model for policy. This may be a major stumbling block to implementation (Klein and Roe are studying this problem).

Concluding Discussion

This paper has presented a mathematical and verbal discussion of mathematical programming sector models. In the formulation, both price and quantity of factors and products are endogenous variables. This is accomplished through the maximization of the area between the product demand and supply schedules. The optimal solution to the model represents a simulation of the industry under the assumption of perfect competition.

Perhaps the principal question that should be addressed in conclusion is: "Why use this technique?" This question is separable into two aspects. First, why use this objective function in a mathematical programming model? Second, why use a mathematical programming model? The most obvious reason for the use of this objective function over others is its behavioral implications are consistent with theoretical economic behavior of the sectoral participants. Thus, a model with this objective can be used to simulate producer response to policy. To impose the "policy objective function," e.g., maximize employment, would create an idea of the maxima that could be obtained but not how it would be obtained by policies directed toward the sector.

The second question to be addressed is: Why use the mathematical programming approach? Fundamentally, the mathematical programming approach should not be used when simple models can do the task at hand. Following Shumway and Chang, "Apparently greater realism in the LP's specification . . . is required to improve substantially on simple econometric models where the latter are also appropriate" (p. 376). We would like to add to this the qualification that "appropriate" includes the fact that data exists for the econometric model estimation. Thus, a mathematical programming model of the above type is attractive in cases where policy analysis is to be done and projections from historical data are not possible due to lack of a data base adequate for statistical analysis of this policy or due to a lack of historical experience with a policy. The mathematical programming sector model relies upon economic theory, building up from producer level data, formally recognizing the potential conflict between government and producer objectives yielding a consistent set of sectoral results within the context of a policy change.

The development of such a powerful and useful tool can be costly. The data requirements are extensive. If resources do exist, however, development of a mathematical programming sector model can be beneficial to both researchers and policy makers.

tration levels in excess of 3%, there could be substantial adjustments relative to the 1947 intensity level. Consider the case for $C = 20$. Advertising intensity would have increased 125% over that of 1947 with no change in concentration. What is apparent in figure 3 is the increased importance of advertising across most industry structures.

Conclusion

The estimates in table 2 provide strong support to the positive relationship between advertising and concentration. A mapping of the empirical results back to table 1 provides some insight as to the alternative effects concentration may have had on both ϵ_a and ϵ_d. Clearly, the alternatives to the right of the diagonal in table 1 are now deleted. The argument that advertising is reduced as concentration increases could only occur if advertising is substituted for price competition indicating that $\partial|\epsilon_d|/\partial C < 0$. It does, however, appear somewhat contradictory to argue that advertising declines in response to rival advertising and simultaneously argue that advertising is substituted for price competition. In contrast, the positive relationship between intensity and concentration is consistent with increases in advertising effectiveness (i.e., $\partial\epsilon_a/\partial C > 0$) and increased nonprice competition (i.e., $\partial|\epsilon_d|/\partial C < 0$). While the empirical evidence is clear as to the final intensity response, conclusions relating to the elasticity response are still tentative.

The empirical evidence failed to show any unique adjustments for food industries that differed significantly from the broader category of durable and nondurable products. Advertising intensity has increased across all concentration levels. The model does facilitate separation of the importance of advertising among manufacturing industries as a result of structural change within industries versus technical changes with the advertising industries where at least part of the shifts over time are due to technical changes in the advertising industry. It is relatively easy to calculate how much of the adjustment in intensity was due to concentration changes versus the time proxy variable. This in turn suggests where public advertising policy emphasis should be directed, assuming that such policy exists and/or is needed. Likewise, the significant difference between consumer and producer goods suggests that if greater governmental scrutiny of advertising is forthcoming, it most likely will be directed toward the consumer goods industries.

Distribution Cost Reduction as an Incentive for Coal Conversion

Jerry E. Fruin, Richard A. Levins, and Douglas Wilson

Declining natural gas supplies and uncertainty over future oil supplies have led to a federal energy policy of encouraging increased coal use. Administration policies have so far been confined to direct orders requiring electric generating stations and very large industrial plants to use coal. However, financial incentives to reduce the high capital costs required to convert from gas or oil to coal also have received wide discussion.

On the other hand, action to encourage conversion to coal by reducing its delivered cost has received relatively little attention. This is surprising, as annual coal costs will greatly exceed the amortized capital cost of coal conversion at a typical installation. Cost of coal at the mine may not be the most important consideration in reducing delivered coal prices. For example, in Minnesota the transportation and related handling costs of coal are usually greater than the price of coal at the mine.

This paper will examine the extent to which delivered coal prices in southern Minnesota (fig. 1) could be reduced if a more efficient coal distribution system were established for potential users. The effect of such action on the economic attractiveness of coal conversion then will be compared to those of public subsidies to reduce initial conversion costs. It will be shown that the financial equivalent of large direct subsidies for coal conversion can be achieved through gains in coal distribution efficiency at less expense to the general public.

Coal Use and Distribution in the Study Area

Coal use in southern Minnesota is currently 4.7 million tons per year. Most of the coal is used by a small number of electrical generating plants. The 1985 coal use in the study area could grow to 15.7 million tons annually when natural gas is curtailed to some 300 industrial and commercial users who now rely on oil or propane as an alternative fuel. Of the potential 1985 demand, 13.6 million tons already are committed. The remaining 2.1 million tons are potential coal use by 300 natural gas users who must decide among fuel oil, propane, and coal as their gas supplies are curtailed.

Most of the coal currently used in southern Minnesota is from the Powder River Basin in Montana and Wyoming or from southern Illinois and western Kentucky. Coal from eastern sources has been declining in relative importance, primarily because of its high sulfur content and relatively high price. The analyses in this paper assumes that the trend to western coal will continue and that new coal users will be supplied by mines in Montana and Wyoming.

Virtually all of the coal leaving Montana and Wyoming moves by rail. Many large-volume natural gas and petroleum customers cannot receive fuel by rail and would have to take delivery by truck if they converted to coal. However, existing coal terminals in the Twin Cities area with train-to-truck transloading capabilities are operating at or near their permitted capacities. Without expansion in terminal capacity, this group of potential coal customers cannot convert to coal no matter what financial incentives they may be offered.

Most of the potential coal customers who can receive coal by rail face high rail rates because their individual coal consumption is too low for them to qualify for volume rates. The trainload and unit train rates shown in table 1 are 50% to 60% of the single car or 15-car rates.[1] Major savings are available to shippers who have access to such rates. In fact, the difference in cost between the single car and unit train rate is greater than the cost of the coal at the mine.

Transshipping Terminals

A central coal terminal serving several smaller users conceivably could generate sufficient volume to qualify for unit train rates. However, a substantial investment in high speed unloading equipment is required in order to take advantage of the unit train concept. The minimum capital cost of a facility that can handle unit trains and store and transship or process a single grade of coal approaches $8

Jerry E. Fruin is an assistant professor, Richard A. Levins is a research specialist, and Douglas Wilson is a graduate assistant in the Department of Agricultural and Applied Economics, University of Minnesota.

Paper 10743 of the Miscellaneous Journal Series, Agricultural Experiment Station, University of Minnesota. This paper is based in part on research funded by the Minnesota Energy Agency.

[1] A unit train is a dedicated set of locomotives and cars that remain together from origin to destination and travel at high speeds. Time requirements for loading and unloading are minimal. Major operating and administrative efficiencies are obtained. Trainload shipments provide similar, though smaller, savings.

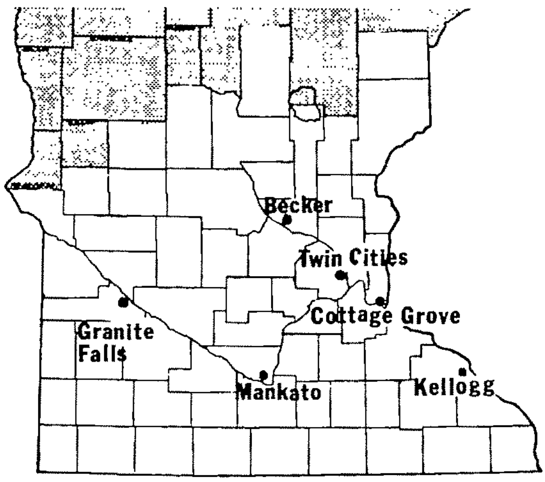

Figure 1. Map of Minnesota study area (unshaded) showing Twin Cities and five possible coal terminal sites

million. Fruin and Crnkovich (1978b) have estimated the minimum capital cost of a rail to truck transshipping facility that can receive, process, and store several grades of coal to be $10 million.

The minimum capital cost of transshipping facilities with both rail-to-truck and rail-to-water was estimated at 12 to 15 million dollars.

Delivery from such a terminal would eliminate the difficulty faced by those customers who cannot receive coal by rail. For coal users who can receive rail shipments, trucking from a central terminal may in many cases be less expensive than paying single-car rail rates for direct shipments from the mines.

An example of the savings possible with such a facility is shown in table 2. The annual cost of owning and operating a facility to transship coal from trains to trucks at an annual volume of 2 million tons per year was estimated to be $1.04 per ton (table 3). The published common carrier rate of $1.85 per ton from the Twin Cities to Elk River, Minnesota (about 35 miles from the center of the Twin Cities) was used to estimate the maximum trucking cost from a centrally located transshipping facility to points in the greater metropolitan area.

Table 1. Coal Rates from Colstrip, Montana, to Selected Destinations in Minnesota

Destination	Type of Shipment	Rate ($/ton)
Minneapolis/ St. Paul	Single car	14.06
Minneapolis/ St. Paul	15 car	13.52
Minneapolis/ St. Paul	105 car trainload	7.61[a]
Becker	Unit train	6.07[b]

Source: Fruin and Crnkovich, 1978b.
[a] Requires 1.1 million tons minimum annual volume. Train must be loaded in less than four hours and unloaded in less than 24 hours.
[b] Requires 2.8 million tons minimum annual volume. Maximum loading and unloading time is four hours.

Table 2. Delivered Cost of Coal to Twin Cities Area Industrial Users from Montana

Cost Item	With Terminal	Without Terminal
	------ ($/ton)	------
Coal, F.O.B. Montana	8.75[a]	8.75[a]
Single car rail shipment	—	14.06
Trainload rail shipment	7.61	—
Transshipping	1.04[b]	—
Trucking	1.85	—
Total	19.25	22.81

[a] *Coal Week*, 21 Aug. 1978. Coal heating value of 8,400 BTU/lb.
[b] Assumes 2 million tons per year throughput.

Even with the extra costs for transshipping and trucking, coal can be delivered for $3.56 per ton less through the terminal than by direct, single-car, rail shipments. The savings may be greater as the rail rate used is an existing trainload rate and not the true unit train rate that would be available if a rail loop and high speed dumping equipment were available. In addition, truck costs would be less to locations nearer the terminal.

Linear Programming Analysis of Terminal Location

The large capital investment required for a unit train terminal makes the transshipping cost quite sensitive to the annual throughput level. At a low annual volume, terminal costs can be high enough to cancel the savings in rail rates. Furthermore, the exact location of the facility is very important as it is necessary to provide lower costs to a large number of potential customers. Customers too far from the terminal will find that higher trucking costs make transshipping uneconomical.

A linear programming model was developed to determine the economic feasibility of potential locations for a new transshipment terminal in the study area, and to estimate the potential savings in delivered coal costs with such a terminal.

Five sites were selected as possible locations for rail-to-truck coal transshiping terminals (see fig. 1). Becker was chosen because a large coal-fired electric generating station with unit-train unloading capabilities is already located there. With additional equipment, the existing terminal could serve smaller customers as well as the power plant. Three of the other sites, Granite Falls, Mankato, and Kellogg, are possible locations for new coal-fired electric generating plants. Terminals could be designed to serve both the power plants and other users. The

[a] A $10 million transshipping facility fully amortized over a 20-year period using an 8% interest rate. Property taxes and insurance were estimated at 3% of the capital costs.

final site, Cottage Grove, was selected because it is close to the concentrated industrial areas of the Twin Cities and has been proposed as a potential terminal site.

Ninety-eight demand points were specified throughout central and southern Minnesota. Demand points were selected based on locations of present and potential industrial coal users. At least one demand point was located in each county with existing or potential coal use. The total 1985 coal demand of all consumers was projected to be 4.3 million tons per year.[2] Of this, 2.2 million tons per year was accounted for by "committed" users, i.e., those that are either now using coal or have definite plans to convert. The remaining 2.1 million tons per year is the potential demand if all industrial natural gas customers in the area converted to coal. Initial model runs assumed that all of the potential demand would be realized; this assumption was modified in later runs to allow for situations with less than 100% conversion to coal.

Coal could move to each destination by direct rail shipment from the mine or by being trucked from any of the five terminal locations. All coal was assumed to originate at Colstrip, Montana. Colstrip is the closest western mine and is within a few miles of the route used by virtually all western coal coming to or through Minnesota. The assumption of this particular single mine source will cause total rail costs to be slightly understated, but should have no effect on terminal site selection or transportation mode selection.

The objective of the model was to minimize total transportation and transshipping costs. The objective function was specified as follows:

$$\sum_{1}^{98} a_k X_k + \sum_{1}^{5} b_j Y_j + \sum_{1}^{5} s_j Y_j + \sum_{j=1}^{5} \sum_{k=1}^{98} c_{jk} Z_{jk},$$

where a_k represents the cost of rail shipment per ton directly from the mine to demand points k, $k = 1, \ldots, 98$; b_j is the cost of rail shipment from the mine to transshipping terminal site j, $j = 1, \ldots, 5$; s_j is the per ton transshipping charge at transshipping terminal j; c_{jk} represents the cost of trucking coal from transshipping point j to demand point k; X_k is the amount of coal shipped directly from the mine to the kth demand point; Y_j is the amount of coal which is shipped from the mine to the jth transshipping terminal; and Z_{jk} represents the coal that is shipped from the jth transshipping terminal to the kth demand point. The objective function is subject to the following constraints:

(1) $$\sum_{j=1}^{5} Z_{jk} + X_k \geq D_k, \; k = 1, \ldots, 98,$$

(2) $$\sum_{k=1}^{98} Z_{jk} \leq Y_j, \; j = 1, \ldots, 5,$$

(3) $$X_k \geq 0, \; Y_j \geq 0, \; Z_{jk} \geq 0, \quad k = 1, \ldots, 98, \; j = 1, \ldots, 5,$$

when D_k is the exogenous annual coal demand of the kth demand point.

The rail rates directly from Colstrip to the terminal sites and most final demand points (a_k, b_j) were taken from Fruin and Crnkovich (1978a). Those demand points which were not covered by tariffs were estimated on a per mile basis from existing rates. The amount of coal demanded determined whether single or multiple car rates were used for direct shipments. The truck rates (c_{jk}) used were selected as representative of area truck rates. Rail and highway mileages were taken from the *Rand-McNally Railroad Atlas* and *Highway Mileage Tables*.

Transshipping charges (s_j) were obtained from Fruin and Crnkovich (1978b). Transshipping costs per ton were estimated to decrease as annual throughput increased until an annual volume of 3.2 million tons was reached, after which costs were constant at 73¢ per ton (table 3).

[2] An additional 11.4 million tons per year of the area's projected 1985 coal demand is accounted for by five large power plants. These plants are large enough to receive high volume rail shipments directly from the mines and would not need a new terminal. Therefore, their coal demand was not included in the analysis.

Results of Analysis

The minimum transportation and handling costs and the resulting shipping patterns were obtained, using a linear programming algorithm. The total coal transportation and handling cost of serving all users was first determined under the assumption that no terminals would be constructed. Minimum cost solutions were then obtained, one at a time, assuming a single transshipping facility was constructed and coal could be shipped to each demand point by rail or by truck from the transshipping facility. The initial solution for each terminal was obtained, using the minimum level transshipping cost of 73¢ per ton. The transshipping cost was then increased on successive runs until it corresponded to the volume level going through the terminal. A similar iterative procedure was used with various combinations of the five possible transshipping facilities. The totals of transportation and handling charges for each case were compared to those of the "baseline" case. Results of selected significant cases are reported in table 4.

The least-cost solution was obtained with a combination of the Becker and Cottage Grove sites. Total transportation and handling charges with this solution were 18.9% lower than the $57 million baseline case. For Cottage Grove, the relatively low transshipping charge ($.81/ton) was due to the large amount of coal being transshipped through the terminal (2.8 million tons). In contrast, the low transshipping charge at Becker ($.73/ton) was due to the existing power plant. Even though only 460,000 tons of coal were transshipped to other users from Becker, 3.0 million tons per year are transshipped for use in electrical generation.

The relative importance of the Becker and Cottage Grove sites in the least-cost solution can be seen by comparing that solution with one including only the Cottage Grove site. Although the marginal savings due to adding the Becker site are relatively small, there are significant advantages for using the site as a terminal. The majority of the transshipping facilities are already present because of the power plant. Construction of the additional facilities for the terminal would only cost $2 million. The simple payback period based on the $700,000 savings would be less than three years. Furthermore, truck traffic from the terminals would originate from two sites rather than one, thereby partially alleviating a potentially serious traffic problem.

Because of their distance from the metropolitan area and the dispersion of the remaining demand points, the economic significance of the Granite Falls, Mankato, and Kellogg sites was relatively small and will not be discussed further in this paper.

In each of the above solutions, it was assumed that all committed and potential users would use coal. It is unlikely that all of the potential users will use coal. The high costs involved in converting heating and energy systems to coal, environmental restrictions on coal use in certain areas, and discoveries of new natural gas supplies could all discourage maximum coal conversion. In any case, some potential users would find conversion unprofitable or environmentally impossible and would continue with their present secondary fuel even as the costs for such fuels rise. A mandatory conversion program is the only realistic possibility for achieving the maximum total demand described in the model.

To demonstrate the effect of only some of the users converting to coal, the total demand for each potential user was cut in half. The total reduction in coal demand was only 1.1 million tons, or 25% of the total amount, because the demand by the committed users was not affected. The least-cost solution of the reduced demand model was the same as before, Becker and Cottage Grove. The total savings over the baseline case were, of course, less because less coal was shipped. However, savings of $6.6 million per year were still possible with this case, as compared to savings of $10.8 million per year in the full-demand model. The Becker terminal, which retained the same transshipping charge as before because of the power plant, reduced its

Table 4. Total Shipment and Savings for Selected Transshipping Alternatives

Transshipping Points	Total Shipments	Savings over Baseline	
	(tons)	($)	(%)
None (baseline) Direct from mines	4,297,176	—	—
Becker Direct from mines	2,739,988 1,557,188	6,538,710	11.5
Cottage Grove Direct from mines	3,127,196 1,169,980	10,094,859	17.7
Becker Cottage Grove Direct from mines	460,836 2,812,970 1,023,370	10,796,359	18.9
Becker Kellogg Direct from mines	2,518,261 642,627 1,136,288	7,562,466	13.3

throughput by only 16%, even though overall coal demand was reduced by 25%. In contrast, the Cottage Grove site reduced its throughput amount by 35% because there was no "baseload" demand by a power plant to guarantee a large throughput and low transshipping charges.

Policy Implications

The economic analysis presented here suggests that coal transportation and handling costs could be reduced substantially if new distribution centers were established. The savings to coal users in southern Minnesota were estimated to be $10.8 million per year if all potential coal users convert to coal and $6.6 million per year if the coal demand by potential users is reduced by half.

The present values of these annual savings streams can be used to compare delivered coal price reductions with "up-front" subsidies intended to defray initial conversion costs. The present values were calculated over a twenty-year period, the assumed life of a new terminal, and at rates of 7% and 16%. The 7% rate was chosen as representative of the cost of public money obtained through revenue bonds; the 16% was taken as representative of the cost of capital to small- or medium-sized firms.

At 7%, the present value of the $10.8 million per year savings for twenty years is $114.4 million. The corresponding value for the $6.6 million savings is $69.9 million. At 16%, the two savings streams have present values of $64.0 million and $39.1 million, respectively.

Thus, it can be inferred that even at the lower annual savings rate, private decision makers should find terminal construction to be as attractive as a one-time $39 million subsidy program. For projects using public funds, such as converting public buildings to coal, the savings would be equivalent to a one-time subsidy program of almost $70 million.

Public action to encourage coal terminal development would be far less expensive than equivalent subsidy programs designed to reduce initial conversion costs. The capital costs of terminals could be financed by revenue bonds which would be liquidated by project revenues. Such bonds might require state guarantees, but the total cost to the public would be negligible if the project were successful and relatively small even if the project failed. On the other hand, up-front subsidies would require either tax credits and allowances or outright state or federal grants. Both substantially reduce the tax revenues available for other purposes.

There also would be other advantages to terminal development over up-front subsidies. Terminals would make coal available by truck to potential customers who cannot receive coal by rail, a problem that is not addressed by subsidy programs now being considered. Furthermore, the benefits from reduced coal distribution costs would accrue to all coal users, not just those which are selected for public payments.

In spite of these benefits, it is not suggested here that establishing coal terminals will in and of itself bring about coal conversion. Air quality restrictions on coal use are not addressed. Furthermore, there is no assurance that the savings from terminal use alone will be large enough to make coal conversion attractive for the private sector. For example, consider the case of an installation using 585,000 gallons of residual fuel oil at 31¢ per gallon and facing the coal costs shown in table 2. For approximately $2 million, it could be converted completely to stoker coal firing and use 5,000 tons per year of western coal at $22.81 per ton. If a terminal were available, the cost could be reduced to $19.21 per ton. The simple paybacks for the conversion investment would be thirty years without the terminal and twenty-three years with it. Even though the terminal would save this user $18,000 per year in fuel costs, it is clear that further incentives would be necessary to induce the example industry to convert to coal (Minnesota Energy Agency, p. 41).

It also is pointed out in this paper that the lowest distribution costs for coal would result if the coal-handling equipment at electric generating stations were used for coal distribution as well. The following problems might arise from such an arrangement: (*a*) the possible unwillingness of a railroad to deliver coal bound for several consignees to a central point without raising rates, (*b*) space and other physical limitations at existing generating stations, (*c*) prohibitions on some utilities from engaging in activities other than public utility services, (*d*) difficulty procuring coal, and (*e*) problems caused by increased truck traffic.

The above problems deserve study on a case-by-case basis before any specific proposals are put forth. Problems of physical limitations, coal procurement, and truck traffic would best be addressed by considering proposed generating stations, rather than existing ones, as terminal sites. Therefore, a generating station's potential as a coal distribution center should be considered in future power plant siting decisions.

Summary

A linear transshipment model was used to determine the extent to which delivered coal prices could be reduced through gains in efficiency in coal transportation and distribution. Aggregate savings for coal users in southern Minnesota of as much as $10.8 million per year were shown to be possible.

It was argued that the savings thus obtained would have the same effect as large direct subsidies to potential coal users in encouraging coal use. A program to reduce delivered coal costs would involve less public funding than subsidies in addition to providing coal delivery by truck to industries not able to receive it by rail. Furthermore, the benefits

from reduced coal distribution costs would accrue to all local users, not just those selected for public payments.

The economic savings possible from improved coal distribution and handling, alone, would in many cases be insufficient to encourage coal conversion in the public sector. Further subsidies and consideration of air quality restraints would almost certainly have to be included along with terminal development in an effective program to encourage industrial coal use. However, this in no way detracts from the fact that the savings in coal distribution costs can be achieved at far less public cost than equivalent direct subsidies.

Economic Trade-Offs and the North Carolina Shrimp Fishery

James R. Waters, J. E. Easley, Jr., and Leon E. Danielson

The North Carolina shrimp resource consists of three major species, brown (*Penaeus aztecus*), pink (*P. duorarum*), and white (*P. setiferus*). Together, they comprise the state's most important fishery. Two of these species exist in Pamlico Sound, the principal fishing area.

The brown shrimp population represents the primary resource in terms of landings and value received. Members of this species use the many creeks and bays along the North Carolina coast as nursery areas during postlarval stages of development. As individuals mature, they migrate into the deeper waters of Pamlico Sound where they become vulnerable to fishing gear. Fishing activity begins in July and continues until the shrimp migrate to offshore waters, generally in late September or early October, at which time they are lost to the fishery.

The pink shrimp population constitutes the second major shrimp species in North Carolina. These individuals enter Pamlico Sound throughout the summer and utilize the Sound as a nursery area for postlarval growth. Pink shrimp achieve commercial size in October and November. During the winter, pink shrimp remain in Pamlico Sound; surviving adults are harvested in May and June before they migrate to the ocean.

Thus, during August and September, brown and pink shrimp coexist in Pamlico Sound, but at different stages of maturation. Pink shrimp utilize the brown shrimp fishing grounds as a nursery area. As a result, precommercial-size pink shrimp are caught incidentally by fishermen harvesting brown shrimp because the fishing gear does not perfectly discriminate between juvenile and adult shrimp. The juvenile pink shrimp culled from the catch are discarded overboard. Most are killed in the landing, sorting, and discard process.

The purpose of this study is to analyze the incidental catch (or discard) problem to ascertain whether discard abatement policies should be instituted during August and September to protect juvenile pink shrimp. Interest is focused on whether or not the range of observed discard rates is sufficiently large to warrant protection. Because of the lack of required data, the study is primarily a simulation analysis.

Economic Trade-Offs

Since Gordon, Scott, and Clark, the effects of common property resource utilization have been well-known. Fish populations are natural resources that are exploited over time. Communal ownership distorts the choice between present and future income because individual fishermen do not consider foregone future income in their cost calculations.

Harvesting brown shrimp when juvenile pink shrimp are destroyed and discarded in the harvesting process reduces the number of pink shrimp available for capture in the future. This reduction in population size implies a smaller expected number of future shrimp to be landed than would occur if discard did not exist. Therefore, the marginal benefit to be estimated when evaluating a discard abatement policy is the increased value of commercial-size pink shrimp expected to be landed in the late fall, the following spring, and, through spawning, in future years. An additional benefit is the potential reduction in future operating costs. A larger population size would increase population density and may make both locating and harvesting shrimp less time-consuming, and, hence, less costly.

Although reducing the cost of foregone future earnings, policies that protect juvenile pink shrimp will impose other costs on the industry. There are three sources of discard prevention costs to be considered when evaluating a discard abatement policy. The primary cost component is the value of commercial-size shrimp not landed during the discard period that otherwise would have been landed. Second, discard policies may increase vessel operating costs. Fishermen who ignore the presence of the juvenile shrimp enable themselves to land and market shrimp at lower cost. Adopting alternative fishing techniques or more selective gear would mean higher costs of production. Third,

Paper No. 5654 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh.

Financial support for the research was provided by the North Carolina Division of Marine Fisheries.

Early input to the study by J. Bruce Bullock is acknowledged, as is the assistance of Connell Purvis of the North Carolina Division of Marine Fisheries. The authors appreciate helpful comments on the manuscript by Tom Johnson, Ron Schrimper, Jerry Carlson, Chuck Knoeber, and the two anonymous *Journal* reviewers.

there may be administrative costs to enforce the policy's regulations. Increased enforcement costs include the expense of employing new enforcement officers and equipment, if needed, and any additional wage payments to existing officers to compensate them for the time required to fulfill their additional duties. Another potential enforcement cost is the increased value of damage that may be inflicted on other species if officers devote relatively less of their time to protecting them from potential violators.

Not all of these potential benefits and costs are included in the analysis, in large part due to lack of data. The most important element in estimating marginal costs and benefits of a discard abatement policy are changes in landings of pink and brown shrimp. Changes in current and future vessel operating costs and enforcement costs are assumed negligible. In addition, fishery biologists consider the environment to be the primary determinant of annual recruitment of shrimp in North Carolina. Hence, the magnitude of this year's catch is assumed to have no impact on next year's catch in the analysis.

The essence of the pink shrimp discard problem is a choice between present and future income. Here, the present is interpreted as the period during which discard occurs. The future is interpreted as the interval during which the benefits of a discard abatement policy will be realized.

The Model

Beverton and Holt advanced the biological model of population change throughout a cohort lifespan. The reduction in population numbers in any instant, τ, is assumed proportional to population size,

$$\frac{dN}{d\tau} = -(M + F)N(\tau). \tag{1}$$

$N(\tau)$ represents population size in numbers, and the coefficients M and F represent instantaneous natural and fishing mortality rates. The natural mortality rate depends on the vulnerability of members to disease, predation, and environmental stress. The fishing mortality rate is a function of the level of fishing activity. Both mortality rates may be assumed constant during short study periods when predator stocks, environmental conditions, and fishing activity are relatively unchanging. McCoy (1968, 1972) and Purvis and McCoy (1974b) have used this model to estimate weekly natural and fishing mortality rates for shrimp in North Carolina.

Integrating (1) yields an expression for the number of individuals remaining in the population and available for capture in each period,

$$N(\tau) = N(\tau_o)e^{-(M+F)(\tau-\tau_o)}. \tag{2}$$

The initial population size, $N(\tau_o)$, is part of the data associated with the problem. Because population size declines exponentially, the maximum age of fish in the fishing ground is predetermined at age T.

$$N(T) = 0. \tag{3}$$

Beverton and Holt adopt the von Bertalanffy weight-age relationship.

$$W(t) = W_{max}[1 - e^{-k(t+a)}]^b. \tag{4}$$

W_{max} represents the maximum weight attained by an average shrimp. The variable a refers to chronological age (in weeks) at time t_o, t denotes weekly intervals, and k and b are parameters. The von Bertalanffy weight equation has been applied on a weekly basis to shrimp in North Carolina (McCoy 1968, 1972; Purvis and McCoy 1974b) and in the Tortugas (Kutkuhn).

The number of shrimp landed, Y, during any week, t, is proportional to average population size during the week, or

$$Y(t) = \int_{\tau=t}^{\tau=t+\Delta t} FN(\tau)d\tau = F\,N(t)\left[\frac{1 - e^{-(F+M)\Delta t}}{M + F}\right], \tag{5}$$

where $\Delta t = 1$ week and $N(t)$ is population size at the beginning of the week. Quantity landed, Q, is simply number landed multiplied by the average weight per shrimp, W.

$$Q(t) = Y(t)W(t). \tag{6}$$

Marginal Benefits

Augmenting the population of pink shrimp at the end of the discard period increases the number of shrimp expected to be landed in the future. Because interest is focused on the increased number of shrimp landed, one can view the number saved from discard as the "initial population size," $N(t_o)$. One can then utilize information about the natural and fishing mortality rates and the weight equation to predict the quantity of these shrimp expected to be landed in each future period.

In documenting the occurrence of juvenile pink shrimp discard, biologists refer to the discard rate, d, defined as the number of juvenile shrimp discarded per commercial-size shrimp landed. The discard rate is used by biologists as their measure of the severity of the discard problem. Policies designed to reduce juvenile pink shrimp discard affect fishermen's incomes by changing the fishing mortality rate and the discard rate during the discard period.[1]

[1] Ordinarily, one would hypothesize alternative policy-induced values for the fishing mortality and discard rates. Then, the number of juvenile pink shrimp saved from discard could be calculated as

$$Number\ Saved = N(t_e) = \sum_{t=t_a}^{t_b} [F_c Z_c d_c N(t_e) e^{-(M+F_c)(t-t_a)} - F_l Z_l d_l N(t_e) e^{-(M+F_l)(t-t_a)}][e^{-(M+F_l)(t_b-t-1)}],$$

The total number of juvenile pink shrimp saved from discard by adopting the ith policy alternative (i.e., the accumulated reduction in juvenile shrimp landings) is approximated as the difference between the number of juvenile shrimp discarded when no specific discard policy applies and when the policy is in effect. The magnitude of this difference depends on the discard rate and the number of commercial-size shrimp landed.

$$(7) \qquad N(t_o) \approx (Q_c A d_c - Q_i A d_i) e^{-M(t_o - t_m)}.$$

The first term represents the number of juvenile pink shrimp that would be discarded if no policy were adopted. The term $Q_c A$ approximates the number of adult shrimp landed. It is the product of the quantity (in pounds) of commercial-size shrimp landed, Q_c, and the average size (number of shrimp per pound) of each marketable shrimp landed. Multiplying by the number of juveniles discarded per adult shrimp landed, d_c, provides an approximation of the number of shrimp discarded.

The second term represents the number of juvenile shrimp expected to be landed incidentally and discarded when the ith policy is enforced. It is the product of the number of marketable shrimp expected to be landed, $Q_i A$, and the discard rate, d_i, that would prevail if the policy were adopted. The difference (7) represents the number of juveniles saved from discard. The factor $e^{-M(t_o - t_m)}$ accounts for those juveniles saved from discard but which die prior to achieving commercial size. Time t_m is taken as the midpoint of the discard period.

Pink shrimp are assumed to be available to the fishery for eight weeks in October and November, and then again in the spring for ten weeks—an assumption approximating observed behavior (Purvis and McCoy 1972). Let V denote the overwintering survival rate. This parameter reflects the percentage of the shrimp population at the end of the fall shrimping season that survive to the first day of the spring season. The overwintering mortality rate must be distinguished from the natural mortality rate, which is an instantaneous decline in population numbers due to natural causes during the fishing season. The overwintering period is assumed to last S weeks. Therefore, the increased quantity of pink shrimp landings due to a discard abatement policy is approximated using

$$(8) \qquad \Delta Q_p = \sum_{t=t_o}^{t_o+8} F_c Z_c W(t)\, N(t_o)\, e^{-(F_c+M)(t-t_o)} + V \sum_{t=n}^{n+10} F_c Z_c W(t-S)\, N(t_o)\, e^{-(F_c+M)(t-S)},$$

where $n = t_o + 8 + S$. The first component represents landings in the fall of pink shrimp saved from discard; the second, those landings in the spring after overwintering. During the overwintering period, pink shrimp do not grow, hence the use of $W(t - S)$ in the second component of equation (8). Time t_o represents the instant at which the discard policy ceases to be in effect.

The value of the increased future landings is the product of the discounted price per pound, $P(t)$ $R(t)$, corresponding to the average-size shrimp and the increased quantity landed during each week.[2] Price is a function of shrimp weight and seasonal factors. The larger the shrimp, the higher the price per pound. Unlike in other states, there is no market price differentiation by species. $R(t)$ is a discount factor of the form $(1 + r)^{-(t+g)}$, where g is the length of the discard period.

In summary, the benefit of a discard abatement policy is approximated using (9).

$$(9) \qquad B = \sum_{t=t_o}^{t_o+8} P(t)R(t)\, F_c Z_c\, W(t)\, N(t_o)\, e^{-(M+F)(t-t_o)} + V \sum_{t=n}^{n+10} P(t)R(t)\, F_c Z_c W(t-S)\, N(t_o)\, e^{-(M+F_c)(t-S)}.$$

The summations here represent discounted values of future shrimp landed in the fall and later in the

where

$$Z_c = \left(\frac{1}{M+F_c}\right)[1 - e^{-(M+F_c)}],$$

$$\text{and } z_i = \left(\frac{1}{M+F_i)}\right)(1 - e^{-(M+F_i)}).$$

The first term represents the number saved during each week within the discard period, $t_a \le t \le t_b$. The second term records the number saved which survive until the end of the discard period. $N(t_a)$ denotes the number of brown shrimp in the fishing area at the beginning of the discard period. The c subscript denotes the current levels of F and d while the i subscript denotes policy-induced values. However, due to the lack of information concerning the magnitude of $N(t_a)$, an alternative method of enumerating the number of juveniles saved from discard was devised.

[2] Annual North Carolina shrimp landings constitute a small proportion of the U.S. total, usually between 2% and 4%. The share is higher during the peak North Carolina landings months of July through September. In testing the effects of North Carolina landings on North Carolina prices, monthly observations were employed for the years 1969–75. Price equations were estimated for different size classes, with few coefficients being significant (hence, North Carolina prices follow those established in the larger Gulf or national market). The North Carolina quantity coefficient was significant, however, for size class 41–50 per pound, the dominant size in North Carolina landings. This equation was estimated in the following form, with t-values shown in parentheses (***, .001; **, .01, *, .05):

$$\ln P_t = -3.43842 - \underset{(-3.43^{**})}{.00015Q_t} - \underset{(-4.87^{***})}{.00779S_{t-1}} + \underset{(2.33^{*})}{.00904Y_t} - \underset{(-2.26^{**})}{.01168Z_t} + \underset{(3.21^{**})}{.01203B_t} - \underset{(-0.41)}{.00129F_t},\ R^2 = .75,$$

where P is ex-vessel price for size 41–50 in North Carolina, deflated by the CPI ($/lb.); Q, total landings, all sizes, in North Carolina (1000 lbs.); S, U.S. inventory of shrimp in cold storage (million lbs.); Y, per capita U.S. income, deflated by the CPI ($/person); Z, shrimp landings in other Southeastern and Gulf States (million lbs.); B, consumer price index for beef products; F, consumer price index for food fish. The price flexibility is evaluated, at the mean of each variable, as −.03. Hence, there is some support for assuming the demand for shrimp in North Carolina is perfectly elastic.

spring. As noted before, the effects of discard policies on vessel operating costs, enforcement costs, and landings in future years are assumed negligible. Further, the possibility of increased brown shrimp landings in October and November is ruled out because brown shrimp virtually complete their migration from Pamlico Sound and out of the fishing area by the end of the discard period (McCoy 1968). Finally, note that benefits are estimated by calculating the impact on aggregate fishery income. It should be recognized that incomes of individual fishermen could be affected differently by a policy's restrictions on fishing activity.

Marginal Costs

The primary cost component of a discard abatement policy is the value of commercial-size shrimp not landed during the discard period that otherwise would have been landed. A management policy reduces the fishing mortality rate, and hence the number of adult and juvenile shrimp landed in each time interval, by changing one or more components in the production function (for example, the minimum legal mesh size). The accumulated reduction in commercial-size shrimp landings throughout the discard period is approximated as the difference[3]

$$\Delta Q_b \approx (Q_c - Q_i) \cong Q_c(1 - x), \tag{10}$$

where Q_c denotes landings that would occur if no policy were implemented, Q_i represents the quantity of brown shrimp that would be landed if the *i*th policy were adopted, and the expression $(1 - x)$ is an assumed percentage reduction in brown shrimp landings. The value of this reduction is simply $P\Delta Q_b$, because demand is perfectly elastic where P is the observed average price during the discard period.

The reduction in current income due to harvesting fewer juvenile pink shrimp is evaluated as zero because there is no market price for juveniles. As indicated earlier the effects of discard policies on vessel operating costs and enforcement costs are considered negligible.

[3] The total policy-induced reduction in shrimp landings is the accumulated reduction from each of the time intervals while the discard policy is in effect, or,

$$\Delta Q_b = \sum_{t=t_a}^{t_b} [F_c Z_c N(t_a) e^{-(M+F_c)(t-t_a)} - F_i Z_i N(t_a) e^{-(M+F_i)(t-t_a)}] W(t) [e^{-(M+F_i)(t_b-t-1)}].$$

At present, there is no information about the magnitude of brown shrimp population, $N(t_a)$, hence the use of an approximation.

Break-Even Discard Rate

To determine whether unregulated discard rates are "too high," an expression for the break-even discard rate, d_e, is derived. The break-even rate is interpreted as that discard rate for which marginal benefits just equal marginal costs of achieving it. If observed discard rates exceed the break-even rate, the benefits of protecting juvenile pink shrimp exceed the costs. Observed rates less than the break-even rate imply that discard abatement costs exceed expected benefits.

Let the policy-induced discard rate be proportional to the unregulated rate,

$$d_i = v\, d_c. \tag{11}$$

Thus, for a discard abatement policy that reduces the discard rate by 70%, $v = 0.3$. To determine the break-even rate, substitute (11) into (7), and (7) into (9), and solve for $d_c = d_e$. We have

$$d_e = \frac{P(Q_o - Q_i)}{G}, \tag{12}$$

where

$$G = \sum_{t=t_0}^{t_0+8} P(t)R(t)\, F_c Z_c\, W(t)(Q_c A - Q_i A) e^{-(M+F_c)(t-t_0)} + V \sum_{t=n}^{n+10} P(t)R(t)\, F_c Z_c\, W(t - S)(Q_c A - Q_i\, A) e^{-(M+F_c)(t-S)}.$$

Application

Several management policies have been suggested as a means of reducing pink shrimp discard. The first ($i = 1$) is a policy of closing the fishery during the period when discard is likely to occur. Closing Pamlico Sound completely eliminates the discard problem, $d_1 = 0$. However, it also entails the highest cost in terms of sacrificed brown shrimp landings, since $Q_1 = 0$.

The second proposal ($i = 2$) is to prohibit shrimping at night when pink shrimp discard occurs. Brown shrimp can be either nocturnal or diurnal, while pink shrimp are nocturnal. Prohibiting night shrimping would virtually eliminate the discard problem except at sunrise and sunset, when members of both species are active. However, if brown shrimp primarily feed at night, this policy would virtually eliminate brown shrimp landings as well as the pink shrimp discard.

In simulating the effects of these two policies, the parameter values shown in table 1 were used. Hypothesized values for the unregulated weekly fishing and natural mortality rates fall within the range of values estimated by McCoy (1968, 1972) and Purvis and McCoy (1974b). Average sizes for juvenile pink shrimp were observed by Purvis and

Table 1. Alternative Parameter Values Used in Simulations

Brown Shrimp Landings Reduced (%)	Discard Rate Reduced (%)	Fishing Mortality Rate	Natural Mortality Rate	Over-wintering Survival (%)	Average Size Number/Pound	
					Brown	Pink
100	100	.20	.25	75	21–25	90
85	75	.15	.20	50	26–30	125
70	50				31–35	
50	25					
25						

Note: Various combinations of values in each column were used.

McCoy (1974a) and Purvis et al. (1977). The discount rate is assumed to be 1% per month or approximately 0.25% per week. Prices used in the analysis were those observed in the 1975–76 season; hence, price changes due to weight increases and seasonal variation are incorporated. Pink shrimp weight in each future period was calculated from the equations estimated by McCoy (1972). No information is available about the proportion of shrimp that successfully overwinter from the fall to the spring season. The simulations presented here assume a 50% survival rate. Increasing the overwintering survival rate from 50% to 75% did not appreciably change the calculated break-even rate. Apparently, the bulk of the benefits of protecting juvenile pink shrimp will be realized before the overwintering period.

Table 2 summarizes the results for the selected situations described in table 1. Each row pertains to a different percentage of reduction in the discard rate. Each column refers to the percent change in brown shrimp landings. Tabled values represent calculated break-even discard rates. Only one entry exists in the first row and column because it is impossible to eliminate completely the entire juvenile shrimp catch without closing the fishery. Situations using other parameter values were examined but are not presented here. Some earlier estimates are contained in Waters, Danielson, and Easley.

Inspection of table 2 reveals that very few of the hypothesized situations generated break-even discard rates as low as 5.0 juveniles discarded per commercial-size shrimp landed. On the other hand, more than 50% of the hypothesized situations implied break-even rates of 10.0 or greater. The calculated break-even rate (including those results not presented here) ranged from approximately 3.5 to 26.3.

Implications for Fishery Management

Table 3 summarizes the results of efforts to document the incidental catch and discard of juvenile pink shrimp. All information was gathered by sampling different shrimping areas with standard fishing gear. Column (3) represents the observed number of juvenile pink shrimp discarded per commercial-size shrimp harvested. Columns (4) and (5) show the average shrimp size by species. Column (5) sometimes includes an average size greater than the minimum commercial size of seventy per pound because not all pink shrimp landed were pre-commercial-size.

Table 3 suggests that discard rates are seldom observed to be as high as 3:1. Although observed discard rates appear small, a rate of 1:1 implies that 50% of all shrimp landed (by number) are discarded. In addition, the pink shrimp vulnerable to being incidentally landed and discarded often grade smaller than ninety per pound. A comparison of tables 2 and 3 reveals that, in general, observed discard rates are less than the computed break-even rates. Hence, marginal costs exceed marginal benefits of protecting juvenile pink shrimp in most

Table 2. Break-Even Discard Rates

Policy	Percent Decline of Discard Rate	Percent Decline of Brown Shrimp Landings: 100	85	70	50	25
1. Close fishery	100	16.3	—	—	—	—
2. Prohibit night shrimping	75	—	14.4	12.4	9.3	5.0
	50	—	15.0	13.4	10.9	6.5
	25	—	15.6	14.7	13.1	9.3

Note: $M = 0.25$, $F = 0.20$, $V = 0.50$; average brown shrimp size is 26–30, average pink shrimp size is 90.

Table 3. Pink-Brown Shrimp Discard Data, Pamlico Sound and Core Sound

Date (1)	Location (2)	Discard Ratio: Number of Juvenile Shrimp / Number of Adult Shrimp (3)	Average Size of Brown Shrimp (number per pound) (4)	Average Size of Pink Shrimp (number per pound) (5)

instances. It does not appear that the incidental catch and discard phenomenon is severe enough under normal conditions to warrant the adoption of policies designed to protect juvenile pink shrimp. However, exceptional situations may arise. Table 3 indicates that, in one case, 9.6 juvenile pink shrimp were discarded for every commercial-size shrimp landed. Hence, biologists may want to continue monitoring the discard phenomenon.

Transfer of Development Rights: A Market Analysis

Leslie E. Small and Donn A. Derr

Increasing concern about the quality of life in urbanizing areas and the impact of urbanization both on environmentally sensitive areas and on the land resource base for agriculture has led some state and local governments to consider policies designed to alter market forces affecting private land use decisions in ways that foster retention of open space. Among these policies is a series of related proposals known as the transfer of development rights (TDR), the generic feature of which is the provision for an increase in the density of urban development in some areas in exchange for the permanent retention of open space in other areas.

The type of TDR program analyzed here provides for a designated open space or "preservation" zone in which urban development is prohibited. As compensation for the resultant reduction in the current market value of their land, owners of land in this zone are issued certificates of development rights (DRCs) which can be sold to any willing buyer. A receiving zone in which these DRCs can be utilized is also delineated. Residential development without the utilization of DRCs is permitted in this receiving zone, but only up to the density limit authorized by the basic zoning ordinance; development to a higher "bonus" density limit requires the utilization of DRCs.

Critical to the implementation of such a TDR program is the compensation issue: there must be a reasonable possibility that owners of land in the open space zone can sell their DRCs at a price which represents some acceptable level of compensation. The determination of that level is a normative issue which will not be dealt with here. Rather, this note examines the nature of the demand for DRCs under a TDR program based on residential development and discusses the relationship between the design of TDR and its potential to provide compensation. The resulting analytical approach is then applied to a case study community in New Jersey.

The authors wish to thank Ken Clayton, Howard Conklin, Larry Libby, Allan Schmid, and two anonymous reviewers for helpful comments on earlier drafts of this paper. All shortcomings of the paper are the responsibility of the authors.

The Demand for DRCs

Decisions regarding the utilization of DRCs would be made by individual developers selecting the optimum density at which to develop. If lot size is a positively valued good for an important segment of the market, then as density increases, the market price of houses of exactly the same physical construction would decrease. Cost per housing unit would decrease because of reductions in the costs of site development (shorter streets, sidewalks, water and sewer lines, etc.) and raw land. Furthermore, developers typically build smaller houses at higher densities, resulting in additional decreases in both revenues and costs. Although various approaches to the analysis of the demand for DRCs have been taken in the literature (Bailey and Ogg, Berry and Steiker, Ervin et al., Field and Conrad), none of them provides for both revenue and cost per housing unit to decline as density increases. They all attempt to analyze the demand for DRCs while either abstracting from, or holding constant, housing quality. But the demand for DRCs depends on the densities at which development occurs, and density is one component of housing quality. This section presents a model which incorporates this relationship between density and housing quality.

The demand model for DRCs is for a single locality within a larger metropolitan area. One basic limiting assumption is that the area in which the TDR program is implemented represents such a small proportion of the total new housing market in a given metropolitan region that housing prices would not be affected by TDR (Berry and Steiker). The cost of DRCs could not, therefore, be passed on to the ultimate consumers of housing. This assumption appears realistic in current situations where TDR might be introduced in only a few locations within a metropolitan area. A second assumption is that zoning ordinances of the minor civil divisions making up the metropolitan area effectively limit residential development to densities below the "bonus" densities permitted under TDR. If this were not the case, the establishment of a "bonus" density by a community implementing TDR could fail to create the desired demand for DRCs, because developers could build at the same density in nearby non-TDR communities.

It is assumed that decisions concerning the utilization of DRCs are made by the relatively small number of competing, profit-maximizing developer-builders who operate in a given community. For each developer, the marginal cost of pro-

ducing housing units at any given density is assumed to be constant until his capacity constraint is reached, at which point the marginal cost becomes greater than the price. This capacity constraint is assumed to be related to the number of housing units constructed, and is independent of the density at which development occurs. For simplicity, we assume that a given developer builds at only one density in a given period. Furthermore, we assume that individual developers expect that their entire production of housing in a given period can be sold at a constant price, although their estimate of that price would be tempered by their knowledge of the amount of housing built in the previous period, and of the planned activities of other developers in the current period.

Production of housing generates a "surplus" defined as the difference between the sale price of the house and all nonland costs (including a competitive return to the developer's capital and managerial abilities). Under perfectly competitive conditions among developers, this entire surplus could be expected to accrue to the owners of land. But in situations where there are continual changes in the housing market and where competition among developers is somewhat limited due to factors which restrict entry (such as capital requirements and transactions costs associated with undertaking activity in a new municipality), a portion of this surplus would accrue to developers. This portion—the difference between the surplus generated by a housing unit and the cost of the raw land needed for that unit—is termed the "residual profit."

In competitive equilibrium, the residual profit should be equal for all densities of housing. In reality, this competitive equilibrium position is seldom likely to exist. Many factors—zoning restrictions, changes in preferences, errors by developers in anticipating market demand (leading to temporary over-building of certain housing types), changes in credit availability (causing the mix of market participants to change), and others—are likely to cause the residual profit to vary among densities at any given point in time. A developer attempting to maximize his net income in a given period would select the density with the greatest residual profit per housing unit.

With TDR, sellers of DRCs would capture some of this residual profit. The maximum amount a developer could afford to pay for the DRCs necessary to build one unit of housing would be the residual profit generated by that unit. But, because he could produce low-density housing (for which no DRCs are required) and capture the entire residual profit, the maximum amount that a developer would be willing to pay for DRCs would be equal to the increase in the residual profit resulting from building at the higher density. The quantity of DRCs demanded by an individual developer in a given time period would depend on the residual profits of housing at different densities, the DRC requirements per housing unit at different densities, and the price of DRCs.

Demand and the Design of TDR

Regardless of the level of compensation provided under TDR, equity among landowners in the open space zone requires that DRCs be distributed in proportion to the estimated reduction in the market value of their land (Ervin et al., Small). This has the effect of defining DRCs in terms of dollars of reduced market value. Let one DRC represent one dollar of reduced land value, and let k represent the desired or acceptable level of compensation expressed as a proportion of the total reduction in land value. In the aggregate, the DRC market could provide the specified level of compensation only if it had the potential to sustain an initial DRC price equal to k, which could therefore be called initial compensation price. This condition does not imply, however, that the actual initial price will be k, since it is not possible to know in advance the actual performance of a private market. The significance of k as the initial compensation price is that at this price, an individual landowner could sell his DRCs immediately upon the implementation of TDR and receive the acceptable level of compensation.

Subsequent to their creation, DRCs are a storable good in fixed supply with no inherent utility in ownership. Regardless of whether they are held by the owners of open space, developers, or speculators, equilibrium in the DRC market therefore requires that the expected DRC price rise over time at a rate equal to the cost of holding DRCs. This would include the opportunity cost of capital, risk, and DRC taxes. Given the initial compensation price (k) and the cost of holding DRCs, the compensation price for DRCs at any point in time is determined.

For developers to be willing to purchase DRCs at any point in time, the DRC price multiplied by the DRC requirement per housing unit must be no more than the increase in residual profit resulting from building at the bonus density. In particular, this condition must hold in the last year in which DRCs are utilized. Thus, the compensation price in that last year (which is determined by k, the cost of holding DRCs, and the length of time over which the DRCs are utilized) determines the maximum DRC requirement per housing unit which is consistent with the desired level of compensation.

Unless there is provision for periodic increases in the required number of DRCs per housing unit, this maximum DRC requirement must apply throughout the life of the TDR program. The longer the expected length of time between the creation of DRCs and the utilization of the last DRC, the lower will be the maximum DRC requirement per housing unit, but the larger will be the number of housing units utilizing DRCs. As this length of time increases, *ceteris paribus*, the maximum number of DRCs utilized during the life of the TDR program first

increases and then decreases. Assuming a constant number of new housing units per year, the maximum number of DRCs demanded occurs for programs designed for the utilization of all DRCs within a fifteen-year period if the holding costs are 7%, and within a ten-year period if the holding costs are 10%.

It is, thus, possible to identify six key factors in the design of TDR: (*a*) the cost of holding DRCs, (*b*) the expected length of time over which DRCs are to be utilized, (*c*) the desired level of compensation (k), (*d*) the expected increase in residual profit, (*e*) the expected rate of housing construction at the bonus density, and (*f*) the average reduction in land values per acre in the open space zone. Given the cost of holding DRCs, the TDR program should be designed for a period of DRC utilization no longer than would result in the maximum utilization of DRCs. Once this planned period of DRC utilization has been established, knowledge of the desired level of compensation and of the expected increase in residual profit can be used to establish the DRC requirement per housing unit. This, together with the estimated number of housing units to be built at the bonus density during the period of DRC utilization, gives the estimated total number of DRCs utilized. This should be no greater than the number of DRCs created, which, by definition, equals the initial reduction in market value in the open space zone. Given the average reduction in land values per acre, the acreage of open space that can be supported by the TDR program at the desired level of compensation can then be determined.

Analysis of a Case Study

To gain insight into the potential and limitations of TDR, a case study for the Township of South Brunswick, located in Middlesex County, New Jersey, was undertaken. A proposed TDR ordinance (which has not been implemented) was developed (Nieswand et al.), followed by an examination of the market aspects of the ordinance, in which the conceptual approach discussed above was applied to the specifics of the case situation (Small et al.).

South Brunswick's location in the Boston-Washington corridor, about midway between New York City and Philadelphia, contributed to a rapid rate of growth since 1950. Since 1960, its population has grown at about 3.1% per year. With a current population of about 18,000 people, the township has a population density of about 435 people per square mile. About 11,300 acres—43% of the land in the township—is devoted to agricultural production. Another 8% of the land is classified as vacant. There is interest in retaining the land base necessary for a viable agriculture, as well as protecting the underground water supply of the township by limiting development on important aquifer-recharge areas. All of the township is zoned, and urban development has been in close conformance to the densities permitted by the zoning ordinance.

The TDR proposal for South Brunswick called for an open space zone of approximately 6,700 acres and receiving zones of 1,900 acres. Based on the current zoning of the open space zone (agricultural/residential with maximum gross densities ranging from 0.32 to 1.3 housing units per acre), approximately 4,200 potential housing units would be eliminated. The current zoning of the receiving zones (agricultural/residential with maximum gross densities ranging from 0.32 to 1.8 housing units per acre) would permit approximately 2,000 new housing units. With the use of DRCs, maximum densities could rise to between 3.0 and 5.0 housing units per gross acre, increasing by 6,700 the number of potential new housing units in the receiving zones. The net effect of the TDR ordinance would thus be an increase of about 2,500 in the number of new housing units permitted in the township. In addition to the 8,600 acres in the open space and receiving zones, there are 5,400 acres of residentially zoned land (including more than 500 acres on which townhouses and garden apartments are permitted) for which the zoning would remain unchanged.

Determining the magnitudes of five of the six items of information needed to evaluate the South Brunswick TDR proposal presented no difficulties. The real cost of holding DRCs was estimated to be from 7% to 10%. This included 2% for DRC taxes, 2% to 3% for an inflation-free return to a low-risk investment; and 3% to 5% as a return to the risk of holding DRCs. The expected length of time of DRC utilization was chosen to maximize the demand for DRCs. This period—which depends on the cost of holding DRCs—ranged from 15 to 10 years. In the absence of any clear agreement on the acceptable level of compensation, alternative values of k, between zero and one, were considered. Past rates of population growth and housing construction along with alternative estimates of future population growth and household size were evaluated to develop three alternative rates of total housing construction: 75, 150, and 250 units per year. It was assumed that three-fourths of these units would be built at the bonus density. Based on information generated in the development of the TDR proposal (Nieswand et al., pp. 73–75, 89) and on agricultural use-value appraisals conducted in Burlington County, New Jersey, as part of a pilot project for the purchase of development rights by the state government, alternative estimates of the average reduction in the market value per acre in the open space zone of $3,150 and $2,500 were developed.

Much of the analysis was devoted to estimating the one remaining factor, the increase in residual profits that could be expected in South Brunswick. Three types of housing at densities which large-scale developers could expect as options in South Brunswick were selected: single-family detached housing, at six densities ranging from 1.3 to 5.0

houses per gross acre; townhouses (single-family attached units) at three densities from 6 to 10 units per acre; and two-story garden apartments at four densities from 10 to 18 units per acre. For each density selected, the specific type and size of the housing unit were chosen on the basis of a market survey of new housing developments.

An estimate of the residual profit for each of the thirteen housing type and density combinations was developed from estimates of total costs and revenues. A hypothetical subdivision layout was prepared for each of the thirteen alternatives. To incorporate the economies of size associated with tract developments, each layout contained approximately 180 units. The arrangement of the dwelling units at the various densities was held as nearly constant as possible. The physical requirements for the components of site development and housing construction were determined from the layouts, using the requirements of South Brunswick's ordinances.

Some of the site development costs were estimated on the basis of information provided by the New Jersey Builders' Association, landscape contractors, and officials of utility companies. The remaining site development costs and the costs of the structures were estimated by Wood and Tower, Inc., of Princeton, New Jersey, a firm that specializes in construction cost estimation. Municipal fees were based on the fee schedules of South Brunswick. Estimates of the finance costs and of the market value of the capital, management, and labor provided by the developer were made on the basis of information gathered from individuals involved in real estate finance. Data on recent transfers of land in South Brunswick were evaluated to provide information on the cost of raw land.

Estimates of the potential revenue for the single-family and townhouse subdivisions were made on the basis of information gathered on current sales of new housing in South Brunswick and surrounding areas and from interviews with real estate brokers. Estimates of the potential revenue for the garden apartment subdivisions were made on the basis of a gross rent multiplier, which converted the effective annual contractual rent into an estimate of market value.

Results

The results of the investigation into the market conditions for South Brunswick are presented in table 1. The residual profits in column 7 indicate the relative attractiveness to developers of alternative housing types and densities under the market conditions prevailing in South Brunswick during the first six months of 1977, and are estimates of the maximum amounts that developers could afford to pay for DRCs. The figures indicate that low-density, single-family detached housing is the most attractive to developers, with a residual profit of about $4,700 per housing unit. The estimated residual profit falls to about $2,300 per unit for the high-density, single-family housing types, and to $1,000 per unit for the low-density townhouses. Higher density townhouses and garden apartments appear unprofitable. These results are consistent with activity in the housing market in South Brunswick,

which has been limited largely to low density single-family houses. Concern over rent control and the need for increased contractual rent to cover rapidly rising construction costs has adversely affected investor demand for apartments.

These results suggest that at the time of the study, the TDR program would have failed to generate any significant demand for DRCs. The results, however, are highly sensitive to changes in the housing market. The $2,500 difference in the residual profit between the most profitable density (1.3 units per acre) and the highest density of single-family detached houses could be eliminated by either a 3.5% reduction in the price of the dwelling at 1.3 units per acre, or an increase of 6.1% in the price of houses built at 5.0 units per acre. Given the volatility of the housing market, substantial changes in the relationship among the residual profits at various densities might take place during a relatively short time span, resulting in a highly unstable demand for DRCs.

Assuming that changing market conditions might lead to a structure of residual profits favorable to high-density, single-family detached housing, the results of the housing market study provide some insight into the range of values likely for the increase in residual profits. The residual profits estimated for the single-family detached houses range up to $4,800 per house, with the largest difference between any two single-family densities being $2,600. These figures suggest that under market conditions in South Brunswick favorable to TDR, the increase in residual profit from building at the bonus density is not likely to exceed $5,000. An increase on the order of $1,000 to $3,000 per housing unit would appear more realistic.

Based largely on physical criteria, an open space zone of 6,700 acres was proposed for South Brunswick. Using the most favorable estimate of the cost of holding DRCs (7%), of the rate of construction of new housing (250 units per year, three-fourths of which are assumed to be built at the bonus density), of the increase in residual profit per unit ($5,000), and of the reduction in land value in the open space zone ($2,500 per acre), an open space zone of 6,700 acres implies a value of k of 0.30. Alternatively, using the same assumptions listed above, the maximum size of the open space zone would be 4,077 acres if k is 0.5, and 2,039 acres if k is 1.0. If the rate of housing construction is assumed to be at the moderate level of 150 units per year, of which three-fourths are at the bonus density, the open space that could be retained by TDR would be 2,446 acres if k is 0.5 and 1,233 acres if k is 1.0. Under these assumptions, an open space zone of 6,700 acres would imply a value of k, of 0.18. Thus, even with favorable market conditions, severe constraints exist either on the amount of open space that could be retained or on the level of compensation that could be expected.

Conclusions and Implications

The basic presumption underlying virtually all TDR proposals—that high densities are more attractive to developers than low densities—needs careful empirical investigation in any given situation where TDR is being proposed. The market investigation for the South Brunswick case study led to the conclusion that high density was less attractive than low density at the time of the study.

The amount of open space that can be supported by a TDR program depends on the reduction in land values in the open space zone, the proportion of that reduction deemed acceptable as compensation, the cost of holding DRCs, the expected length of time over which DRCs are to be utilized, the increase in residual profit at the bonus densities, and the rate at which new houses are built at these densities. The analysis of the case study suggests that the economics of the housing and land markets may place severe constraints on the amount of open space that a TDR program can support unless low levels of compensation are accepted.

Consideration of the above factors can lead to the design of a TDR program that has the potential to maintain an average price level consistent with the desired degree of compensation. It does not, however, guarantee either that the aggregate level of compensation forthcoming will be equal to the desired level or that each individual participant in the market will receive the desired level of compensation. Implicit in the reliance on a private DRC market is acceptance of the fact that some sellers of DRCs will gain by selling when prices are favorable, while others will sell during periods of depressed prices. Such occurrences are especially likely in view of the probable volatility of the DRC market.

Finally, there is no reason to expect that the amount of open space that a TDR program could support would be socially optimal. Under TDR, the cost of the open space is paid for from the increases in the residual profits of developers. These increases are not a function of the benefits of the open space, but rather are a function of the restrictions on density which exist in the original zoning, and on the demand for higher density housing. Thus, even private costs and benefits of open space would not be equated by TDR. But even if they were, the amount of open space which TDR could support would be less than the socially optimal amount, due to the fact that many of the benefits of open space have characteristics of public goods, and would thus be external to the participants in the DRC market.

Recreation Demand Equations: Functional Form and Consumer Surplus

Rod F. Ziemer, Wesley N. Musser, and R. Carter Hill

The subject of recreation demand has increasingly attracted the attention of economic research. The demand equations resulting from this research follow the Hotelling-Clawson model of recreation demand, in which occasions (or days) recreated is specified as a function of average cost and average distance traveled per occasion and various combinations of other explanatory variables. Linear, quadratic, and semilog functional forms have been used widely in empirical applications of this model. Linear specifications have been employed often for computational or analytical ease (Burt and Brewer; Brown, Singh, and Castle; Cicchetti, Fisher, and Smith; Clawson and Knetsch). Other functional forms have been chosen frequently on the basis of statistical significance and consistency of the coefficients with theoretical expectations. Examples of a semilog form are Batie, Jensen, and Hogue; and Sawyer and Shulstad. A quadratic expression was chosen by Gum and Martin. A fourth functional form, log-log, also has appeared (Kalter and Gosse; Smith; Wetzstein and Green), but will not be considered here for reasons to be developed later. As the results of this study will demonstrate, the choice of functional form can have a significant effect on consumer surplus values derived from recreation demand equations.

This paper presents a set of decision criteria for the choice between three popular functional forms that have been employed previously in recreation demand equations. The choice between linear and quadratic forms can be made via conventional hypothesis-testing procedures. The Box and Cox transformation procedure often allows choice between linear, semilog, and other power transformations of the dependent variable. The consequences of the choice of a particular functional form on consumer surplus also are investigated. The plan of the paper is first, to specify an appropriate set of regressors; second, to choose an appropriate functional form; and, finally, to demonstrate the effect of functional form on consumer surplus estimates derived from regression cost coefficients of recreation demand equations.

Rod F. Ziemer is a graduate research assistant, Wesley N. Musser is an associate professor of agricultural economics, and R. Carter Hill is an assistant professor of economics at the University of Georgia.

The Choice of Regressors

An initial problem in specifying any demand equation is the choice of an appropriate set of regressors. For the purposes of this study, it was desired that the selection process be consistent with both economic theory and previous recreation demand studies. From standard neoclassical demand theory, demand equations can be derived which express quantity of a particular commodity consumed as a function of the price of the commodity, prices of related commodities, household income, and other variables—usually socioeconomic in character, which are related to systematic changes in preferences. An example of such a variable would be education. Considering average cost, a suitable proxy for the price of a recreation occasion, the Hotelling-Clawson model, and related models, can be specified within a neoclassical framework. The relevant quantity variable in neoclassical analysis of recreation is number of occasions or trips, rather than days recreated (McConnell).

Given these considerations, number of occasions demanded in this study was specified as a function of average cost per occasion, education and income. Average distance traveled per occasion was also included as an independent variable as a proxy for time spent in travel which may represent an opportunity cost to the recreator (Cesario and Knetsch; Knetsch and Cesario; McConnell; Dwyer and Bowes; Dwyer, Kelley, Bowes). A review of past studies involving recreation demand equations supports the use of the set of regressors chosen for the analysis used in this study (Brown, Singh, Castle; Brown and Nawas; Cicchetti and Smith; Edwards, et al.; Gum and Martin; Kalter and Gosse; Smith; Stevens).

The Choice of Functional Form

Another specification problem involves the selection of an appropriate functional form. As Zarembka (1968) noted in an early application of the Box-Cox transformation, economic theory provides little guidance on appropriate functional form for demand functions. Sinden made a similar observation in specific reference to recreation. Subsequently, McConnell noted that demand theory does

Table 1. Regression Results for Demand Equations for Warm-Water Fishing in Georgia

	(12.61)***	(−5.26)***		(−2.22)**	(−2.27)**	(2.26)**	(1.87)*	(3.18)***	(.95)

Note: Number of Observations = 339. *** denotes significance at the .01 level, ** denotes significance at the .05 level, and * denotes significance at the .10 level.

require that the functional form must allow the cross-partial derivative of quantity with respect to price and income to be nonzero. However, all forms used in previous research can be modified to meet this condition. Historically, linear models have been used principally, although quadratic models (involving the inclusion of average cost squared), semilog models (involving the natural logarithm of the dependent variable), and log-log models have been considered. A discontinuous income variable, constructed by recreation survey respondents indicating an appropriate income range, prevented the consideration of a log-log form for this study.[1] Three possibilities, therefore, are considered:

(1) Linear: $Q_i = \beta_0 + \beta_1 AC_i + \beta_2 D_i + \beta_3 I_i + \beta_4 E_i + u_i$,

(2) Quadratic: $Q_i = \beta_0 + \beta_1 AC_i + \beta_2 (AC_i)^2 + \beta_3 D_i + \beta_4 I_i + \beta_5 E_i + u_i$, and

(3) Semilog: $\ln Q_i = \beta_0 + \beta_1 AC_i + \beta_2 D_i + \beta_3 I_i + \beta_4 E_i + u_i$,

where Q_i is quantity of recreation occasions demanded for the ith household, AC_i is average monetary cost per occasion, D_i is average distance traveled per occasion, I_i is income, E_i is years education, and u_i is a stochastic error term.

The recreation activity considered was warm-water fishing in Georgia. All data, which were for 1971, were derived from a previous study of wildlife recreation in the southeastern U.S., completed by the Environmental Research Group at Georgia State University in 1974. From the total Georgia sample, 339 responses from households that participated in warm-water fishing were used as the basis for this study. Participation rates varied from 1 to 400 annual household occasions.

Ordinary least squares results for the three specifications considered are presented in table 1 (t-scores appear in parentheses). Range definitions for the income variables are presented in table 2. A value of one was given to that income variable which corresponded to the respondent's income level and a zero to all other variables. The first income dummy was omitted from each specification and an intercept term included.

Equations (1) and (2) do not meet the theoretical requirement derived by McConnell. To analyze this effect, sets of interaction variables between price and the income dummies were added to these equations. These specifications were estimated with ordinary least squares and the significance of the sets of additional variables tested. The appropriate F statistic was .47 for the linear equation and .31 for the quadratic equation. Because these sets of variables add no significant explanatory power, further analysis is based on the results in table 1 since these specifications are consistent with past research.

[1] Using midpoints of the income ranges employed in the survey questionnaire was considered, but an appropriate value for the open ended "over $20,000" interval could not be determined. For a discussion of the choice between semilog and log-log forms, see Smith.

Table 2. Range of Income Dummies Used in Regression Analysis

Variable	Range
	($)
1	Under 5,000
2	5,001 to 10,000
3	10,001 to 15,000
4	15,001 to 20,000
5	Over 20,000

From table 1, it is not readily apparent which specification is superior. A comparison between the linear and quadratic forms is fairly straightforward. Because the linear and quadratic models differ only by the inclusion of the squared average cost variable, one appropriate test between these two functional forms is provided by the test of the hypothesis that the coefficient of average cost squared is zero. The appropriate t-statistic has the value 1.56 indicating there is no significant difference between the linear and quadratic forms at the .10 level of significance. However, the choice between the linear and semilog forms is not possible by any analysis-of-variance treatment. Thus, the analysis of Box and Cox is used for the comparison between the linear and semilog functional forms in the next section.

A General Transformation Approach

The Box and Cox transformation procedure provides a basis for discrimination between various functional forms. Box and Cox consider the model:

$$(5) \qquad \mathbf{y}^{(\lambda)} = X\beta + \mathbf{u},$$

where X is a matrix of untransformed independent variables, β is a vector of unknown coefficients, $\mathbf{u}$ is an error vector whose elements are normally and independently distributed with mean zero and variance σ^2, and $\mathbf{y}^{(\lambda)}$ is a vector of dependent variables transformed as follows:

$$(6) \qquad \mathbf{y}^{(\lambda)} = \begin{cases} \dfrac{\mathbf{y}^{(\lambda)} - 1}{\lambda} & \text{if } \lambda \neq 0 \\ \ln y & \text{if } \lambda = 0. \end{cases}$$

A λ value of one can be associated with a linear specification and a value of zero with a semilog specification. The transformations described in equation (6) hold for $\mathrm{y} > 0$. Estimates of β, σ^2, and λ, a constant power transformation parameter, can be obtained by regressing $\mathbf{y}^{(\lambda)}$ on X for given λ and then choosing the value of λ which maximizes the concentrated log likelihood function

$$(7) \qquad L_{\max}(\lambda) = \tfrac{1}{2} n \ln \hat{\sigma}^2(\lambda) + (\lambda - 1) \sum_{i=1}^{n} \ln y_i,$$

where n is number of observations and $\hat{\sigma}^2(\lambda)$ is the least-squares estimate of σ^2 for a given λ (Zarembka 1974, p. 86). Zarembka (1968 and 1974) recommends choosing alternative values of λ over a reasonable range, regressing $\mathbf{y}^{(\lambda)}$ on X, and then finding the transformation that maximizes the value of $L_{\max}(\lambda)$. It is also convenient to plot $L_{\max}(\lambda)$ against λ as recommended by Box and Cox (p. 216). A $100(1 - \alpha)$ percent confidence region about $\hat{\lambda}$ is given by

$$(8) \qquad L_{\max}(\hat{\lambda}) - L_{\max}(\lambda) < \tfrac{1}{2}\chi_1^2(\alpha)$$

where $\tfrac{1}{2}\chi_1^2(\alpha) = 1.92$ for $\alpha = .05$. One way to test the hypothesis $\lambda = \hat{\lambda}$ at a specific significance level is to observe whether λ falls within the $100(1 - \alpha)$ percent confidence region.

Following the procedure outlined above λ was varied from -2 to $+2$ in increments of .10 and least squares regressions run using the Georgia warm-water fishing data for the variables discussed earlier. A plot of the log likelihood function is presented in figure 1. The maximizing value of λ is zero, which implies the semilog specification is the appropriate functional form. The 95% confidence interval for λ, equation (8), indicated even λ values of .1 and $-.1$ could be rejected at the $\alpha = .05$ significance level clearly suggesting the linear form ($\lambda = 1$) as inappropriate for the data.[2]

Functional Form and Consumer Surplus

The average cost regression coefficient obtained from recreation demand equations is often used to determine the value of recreational resources in terms of consumer surplus. The valuation technique, often called the Hotelling-Clawson approach, involves utilizing the average cost

[2] At $\lambda = 0$, $L_{\max}(\lambda) = -1034.37$; for $\lambda = .1$ and $\lambda = -.1$, $L_{\max}(\lambda) = -1037.27$ and -1038.18, respectively. The $\alpha = .05$ critical value for $L_{\max}(\lambda)$ was -1036.29.

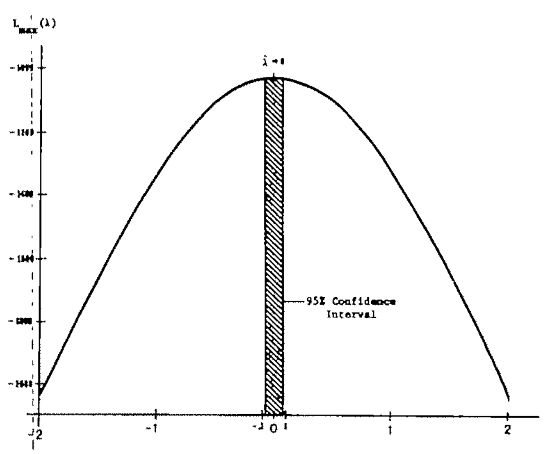

Figure 1. Values of the maximum likelihood function

coefficient as a measure of recreationists' sensitivity to an added cost such as a site entrance fee. According to this technique, a linear equation for the estimated number of occasions demanded becomes

$$(9) \quad \hat{Q}_i = \beta_0 + \beta_1 (AC_i + c) + \sum_{k=2}^{J} \beta_k X_{ik} + u_i,$$

where $\hat{Q}_i$ is the estimated number of occasions demanded by the ith individual, AC_i is average cost, c is added cost, $\sum_{k=2}^{J} \beta_k X_{ik}$ is the sum of other independent variable effects, and u_i is an error term. Gum and Martin suggest subtracting equation (1) from (9) to derive an estimable relationship. Substituting b as an estimate of β_1 and simplifying, the resulting relationship is derived

$$(10) \qquad \hat{Q}_i = Q_i + bc,$$

where Q_i is the actual number of occasions demanded by the ith individual. Integrating this demand curve yields an estimate of consumer surplus

$$(11) \qquad CS_i = \int_0^{c_0} (Q_i + bc)\, dc,$$

where CS_i is consumer surplus for the ith individual and c_0 is the level of added cost which results in no occasions demanded. The value of c_0 can be found by setting $\hat{Q}_i = 0$ in equation (10) and identifying c as c_0. Derivations for the quadratic and semilog forms can be similarly derived. The resulting appropriate demand relationships used for computing consumer surpluses for the quadratic and semilog forms are

$$(12) \quad \hat{Q}_i = Q_i + bc + 2b_2AC(c) + b_2(c)^2, \text{ and}$$

$$(13) \quad \hat{Q}_i = e^{bc}Q_i,$$

where b_2 is the estimated coefficient for the squared average cost term in equation (2). Equations (10), (12), and (13) are presented graphically in figure 2, using the appropriate set of estimated average cost coefficients displayed earlier in table 1. These demand curves are based on a $Q_i = 40$, and an $AC =$ \$2.00, approximately the average number of actual occasions demanded and the mean average cost incurred for the Georgia sample of warm-water fishing participants. Therefore, figure 2 represents the three demand curves, resulting from the functional forms considered, for an average household in the sample.

Consumer surplus was estimated for each of the functional forms described in equations (1), (2), and (3) and summed over all households to obtain sample estimates. The results are presented in table 3.[3] From table 3 and figure 2, it is readily apparent

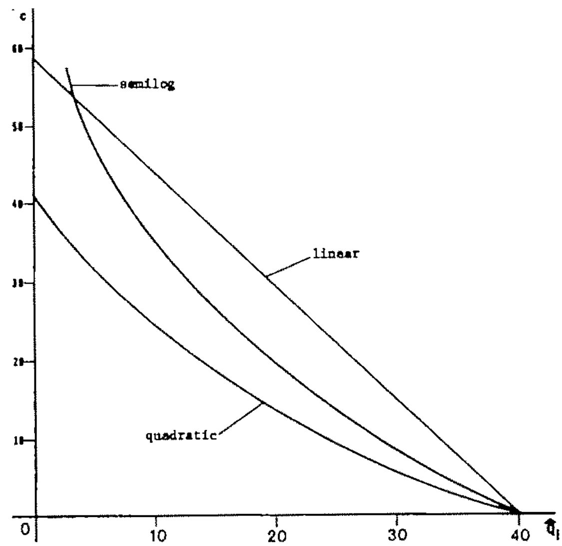

Figure 2. Derived demand curves for warm-water fishing for a representative household in Georgia

that functional form can have a significant effect on estimates of consumer surplus values from recreation demand equations. The linear estimate is approximately three times larger than estimates resulting from either the semilog or quadratic functional forms. The linear estimate of average consumer surplus per occasion is outside the range of values from previous studies compiled by Dwyer, Kelley, and Bowes (pp. 45–64) and may have been questioned on this basis even without statistical consideration of functional forms. However, most previous studies do not clearly indicate that such intuitive considerations of functional forms have been a component of past research. In addition, a previous study has shown that demand parameters used in calculation of consumer surplus can vary among regions, sites, and populations which would confound such intuitive considerations (Ziemer and Musser). This research does indicate that inappro-

Table 3. Consumer Surplus Estimates for Warm-Water Fishing in Georgia from Different Functional Forms of the Demand Equation

Functional Form	Consumer Surplus	Average Consumer Surplus per Occasion
	($)	
Linear	1,004,321	79.09
Quadratic	259,755	20.46
Semilog	335,926	26.46

[3] All figures are sample estimates and would have to be expanded by a population factor to obtain state estimates. An appropriate expansion factor would be equal to the state population divided by the random sample size (which could include nonrecreationists). For our sample this factor is 1558.26.

priate functional form can lead to large errors in estimates of benefits of new public recreation facilities or other public subsidization of wildlife recreation. To avoid such error, it is imperative that surplus estimates be based on the most appropriate functional form.

Conclusions

The purpose of this paper has been to present an analysis of three popular functional forms which have been employed in previous recreation demand studies. The choice between linear and quadratic forms can be made via conventional hypothesis testing procedures. The choice between linear, semilog, and other power transformations of the dependent variable can be assisted by use of the Box and Cox transformation procedure. A secondary objective was to demonstrate the effect the choice of functional form can have on consumer surplus estimates, derived by utilizing average cost regression coefficients from recreation demand equations. Such estimates often are used as an indicator of recreation value and, in some instances, may have had or may eventually have an influence on policy decisions concerning recreation sites and wilderness areas. Results indicate that different functional forms can produce dramatically different consumer surplus estimates. Based on the findings presented here, it is recommended that consideration be given to functional form, as well as to the choice of regressors, when specifying recreation demand equations.

Risk and the Demand for Supplemental Irrigation: A Case Study in the Corn Belt

Jeffrey Apland, Bruce A. McCarl, and William L. Miller

Rapid increases in irrigated acreage in the Corn Belt states during recent years have renewed interest in the associated questions of water resource management and the economic feasibility of supplemental irrigation. Corn plant growth and the associated grain yield is particularly sensitive to moisture stress during pollination (June or July), when soil moisture is especially variable. By reducing moisture stress in these periods, supplemental irrigation can increase and stabilize corn yields.

The focus of most economic feasibility studies of irrigation has been to compare the increases in crop revenues to the costs of irrigating—a cost-benefit approach. It has been suggested, however, that stability of yields, and thus the reduction of risk, should be considered among the benefits from irrigation (Carson, Wheaton, Mannering). Although cost-benefit studies have been used to explain the rapid adoption of irrigation in humid areas by exploring the impacts of prices, costs, and technology changes; no thorough analysis has been made of the impact of risk aversion on the demand by farm firms for supplemental irrigation. This study evaluates the implications of risk aversion for the derived demand for supplemental irrigation of corn using a case study approach.

The Analytical Model

A mathematical programming model of a Corn Belt grain farm was used to generate derived demand functions in the analysis. The riskiness of alternative production activities was considered in the model, which was a slight variant of the MOTAD model developed by Hazell. The following is a generalized formulation of the analytical model (Apland).

$$\text{(1) Maximize: } \mathbf{P}'_1\mathbf{X}_1 - \mathbf{P}'_2\mathbf{X} - ar\,\mathbf{L}'(\mathbf{d}^+ + \mathbf{d}^-)$$

$$\text{(2) subject to: } I_1\mathbf{X}_1 - A_1\mathbf{X}_2 \le \mathbf{0},$$

$$\text{(3) } A_2\mathbf{X}_2 - I_2\mathbf{X}_3 \le \mathbf{0},$$

$$\text{(4) } A_3\mathbf{X}_2 \le \mathbf{b},$$

$$\text{(5) } D\,\mathbf{X}_2 - I_3\mathbf{d}^+ + I_3\mathbf{d}^- = \mathbf{0}$$

$$\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \mathbf{d}^+, \mathbf{d}^- \ge \mathbf{0}.$$

Where $\mathbf{X}_1$ is an n_1x1 vector of outputs, $\mathbf{P}_1$ is an n_1x1 vector of output prices, $\mathbf{X}_2$ is an n_2x1 vector of alternative production activities, $\mathbf{X}_3$ is an n_3x1 vector of variable inputs, $\mathbf{P}_2$ is an n_3x1 vector of variable input prices, A_1 is an n_1xn_2 matrix of coefficients which aggregate $\mathbf{X}_2$ into $\mathbf{X}_1$ (yields), A_2 is an n_3xn_2 matrix of technical coefficients describing the variable input requirements of $\mathbf{X}_2$, A_3 is an n_4xn_2 matrix of technical coefficients describing the fixed factor requirements of $\mathbf{X}_2$, $\mathbf{b}$ is an n_4x1 vector of fixed-factor endowments, D is an n_5xn_2 matrix of observed deviations between expected and actual net revenues for production activities, $\mathbf{d}^+$ is an n_5x1 vector of positive absolute deviations from forecasted net revenues, $\mathbf{d}^-$ is an n_5x1 vector of negative absolute deviations from forecasted net revenues, a is a coefficient which transforms total absolute deviation of returns into an approximation of the standard deviation; $a = \sqrt{\pi n_5/2(n_5 - 1)}$ where n_5 is the number of observations on net revenue used in deviation matrix D, r is the coefficient of marginal risk aversion, I_1, I_2, I_3 are n_1xn_1, n_3xn_3, and n_5xn_5 (respectively) identity matrices, and $\mathbf{L}$ is an n_5x1 vector of ones.

The model above maximizes expected profit less a cost of bearing risk, subject to the technology specified and an endowment of fixed resources. Total absolute deviation[1] (TAD) is used here to form an approximation of the standard deviation of returns and thus has been transformed accordingly by coefficient a. With this transformation and assuming normally distributed deviations in net revenues, $[a\,\mathbf{L}'(\mathbf{d}^+ + \mathbf{d}^-)]$ is an unbiased estimate of the standard deviation of total net revenue (Hazell).

Notice that the coefficient of marginal risk aversion, r, is constant in this linear programming formulation. This parameter is the rate at which the producer will exchange expected net revenue for

[1] TAD has been shown to be an appropriate risk measure in the case of normally distributed returns or a quadratic utility function (Anderson, Dillon, Hardaker). Also, Tsiang (1972) has suggested this measure when the level of riskiness is small relative to the level of wealth. For a more thorough discussion, see Tsiang (1972, 1974) and Levy.

risk. Endogenous factors such as the income level do not influence the coefficient of marginal risk aversion in this formulation. The implications of this assumption will be mentioned later when the analysis is described.

The production model used in this study was an adaptation of a research and extension model of farm production (McCarl, Candler, Doster, Robbins; Brink, McCarl, Doster). Time characteristics of farming were critical in the model. The chronological nature of the production processes was captured by defining activities and resource endowments over twenty-one consecutive time periods in the production period (within one year). In this way, the effects of planting and harvesting dates on yields were captured. For each crop, activities included land preparation, production, employment of part-time labor, reservation of full-time labor, harvest, grain processing, and marketing. Categories of constraining resources included full-time and part-time labor, land, good field time, tractor and harvest time, and irrigation water. The case farm was a 600-acre, two-man grain farm with a medium-sized complement of machinery. Crops included corn, irrigated corn, soybeans, and wheat. More details on the problem formulation are in Apland.

Risk Data

Net revenues for the analysis were generated using time-series price, cost, and yield data. Crop yields were from experimental data on silt loam—a light soil on which the response to irrigation is typically good. These experimental data were assumed to represent the crop technology currently available under good management. The costs of irrigation (fixed equipment costs and variable operating and maintenance costs) were parameterized in the demand analysis and are not included in the per acre net revenue calculations. Other costs related to irrigation, such as additional fertilizer costs, were used in the calculations. Prices and costs were adjusted to the 1975 level using the parity index. Per acre net revenues appear in table 1.[2] Details on the production data are given in Apland.

Analysis of Results

Derived demand functions of the case farm for supplemental irrigation were generated by parametrically altering the cost coefficient on an irrigation supply activity. Irrigation costs were set at zero, then incrementally increased until irrigation was no longer employed. Corn was the only irrigated crop in the model, and high, medium, and low corn price scenarios were analyzed. To explore the impact of risk aversion, the demand functions were generated for decision makers with three different risk postures—risk indifferent (the profit-maximizing case where $r = 0$) and high and low levels of risk aversion ($r = 2$ and $r = 1$, respectively). This range of risk coefficient was analyzed based on the results of previous studies of risk aversion (Brink and McCarl). Although these studies have found no single value of the risk coefficient which best explains the production behavior of farmers, values within this range appear to be most reasonable. With the three corn price levels (at the 1976 expected level and 5% above and below the 1976 expected level), and three levels of the risk coefficient, nine derived demand functions were generated. Table 2 presents the results of the experiments.

Table 1. Actual Net Revenue per Acre by Crop

	Corn	Irrigated Corn	Soybeans	Wheat
1968	99.50	141.50	153.78	75.39
1969	95.11	183.12	128.30	66.66
1970	146.56	205.44	149.14	74.57
1971	−11.47	235.52	164.85	55.29
1972	178.11	186.68	194.97	59.28
1973	186.33	188.16	411.91	100.20
1974	268.19	263.52	255.83	120.31
1975	252.85	263.83	235.38	78.78

Note: Does not include the fixed and variable costs of the irrigation operation, but does include associated costs such as added fertilizer costs.

Figure 1 shows the derived demand functions under the medium corn price scenario. The dotted lines identify the 1976 per acre irrigation cost ($53.50), and costs $10 above and below the 1976 level. Marked differences occurred between the derived demands for the profit-maximizing firm and those in the risk-averse cases. As the coefficient of marginal risk aversion increased from zero, the derived demand functions became more inelastic—changes in per acre costs led to smaller changes in irrigated acreage. Also, optimal acreages in the cost range from $43.50 to $63.50 begin to converge between 150 and 250 acres of irrigated corn. The demand functions display a crossing behavior resulting from the risk-averse firm's tendency to maintain a higher level of crop diversification than the profit-maximizing (risk indifferent) firm.

At the current price of irrigation ($53.50) the irrigation of corn appears to be a rather marginal proposition for the profit maximizer ($R1$). In all cases the price $58.50 causes the profit maximizers demand to go to zero. Thus, an interesting result is that profit maximizers would tend either to not irrigate or to irrigate only small parcels. The model indi-

[2] These net revenue calculations are for a "neutral" combination of planting and harvesting periods—yields and costs in the model change for different planting and harvesting dates and thus per acre net revenues were appropriately adjusted.

Table 2. Acres of Irrigated Corn Grown at Various per Acre Irrigation Costs for Three Levels of the Coefficient of Marginal Risk Aversion (R) and Three Corn Price Levels

Irrigation Cost $/Acre	Acres of Corn Irrigated

[a] Price expectations for 1976 were estimated by using the average of 1974 and 1975 returns. The results were $2.50, $6.00, and $4.23, respectively, for corn, soybeans, and wheat. The corn price was both increased and decreased by 5% in the demand analysis.
[b] $R1$ denotes the risk neutral or profit-maximizing case where $r = 0.0$. $R2$ and $R3$ represent the risk-averse cases where $r = 1.0$ and $r = 2.0$, respectively.

cates that only risk averters would be involved in significant irrigation efforts at current cost levels.

Risk attitude and irrigation price had several impacts on crop acreages. At high irrigation prices with high risk parameters diversification is present between nonirrigated corn and soybeans. At low prices with high risk aversion (r = 2) the acreage was diversified between irrigated corn and soybeans. Increasing (or decreasing) the risk aversion parameter led to a more (less) diversified crop plan between corn (the profit maximizer tended to grow more corn) and soybeans and also led to a substitution of irrigated for nonirrigated corn. Decreasing the irrigation cost tended to lead to the substitution of irrigated for nonirrigated acreage.

The constancy of the marginal risk aversion coefficient (r) should be mentioned at this point. Of course, as irrigation costs change, the farm firm reallocates its resources to maximize managerial income (discounted by risk, in the risk averse case). Over the range of irrigation costs considered in this analysis ($43.50 to $63.50), managerial income changes less than 5%. As such, the risk coefficient is assumed constant over this income range.

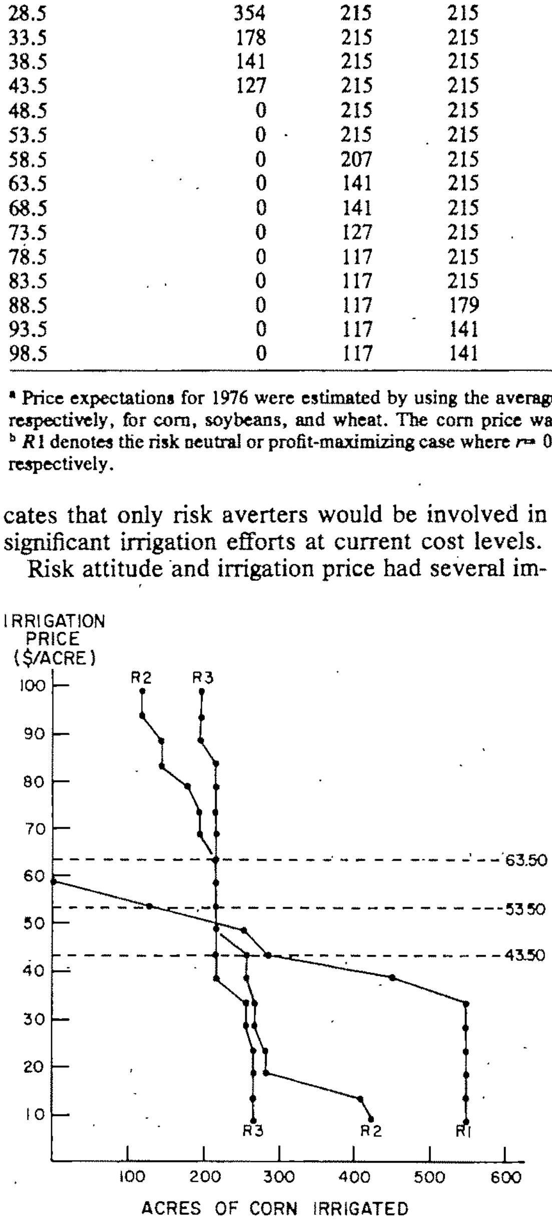

Figure 1. Derived demand functions at medium corn prices for three levels of risk: $R1$ for r = 0.0, R^2 for r = 1.0, and $R3$ for r = 2.0

Conclusions

The results of this analysis indicate that the influence of a manager's risk posture has a marked impact on the firm's demand for irrigation. Any descriptive analyses of the adoption of irrigation should, therefore, consider the implications of risk

aversion. This study suggests that even at high irrigation costs and low corn prices, irrigation technologies may be employed by the rational farm firm manager who is averse to risk. In fact, risk neutral decision makers may not irrigate at current prices; however, risk averters will. Further, the demand for irrigation as a factor of production becomes increasingly inelastic when risk aversion is evident, reflecting the farmer's propensity to eliminate the "risky" nonirrigated crop and to maintain a risk averting diversified crop mix.

Agricultural policy makers are increasingly concerned with farm income stabilization. To the extent that price supports and other policies contribute to income stability, the adoption of irrigation technologies as an aversion to risk would be dampened. Although inferences about the aggregate behavior of Corn Belt farmers in the adoption of supplemental irrigation have not been developed from this microeconomic analysis, this study demonstrates that it is important to address the question of risk in studies of the aggregate demand for irrigation.

The model used in this descriptive analysis has potential in prescriptive applications as well. The programming model could be used in an efficiency analysis of irrigation. By parameterizing technical and economic coefficients, the profitability and risk benefits from irrigating could be "pretested" for a variety of farm classes. Such data could then be used to narrow down the circumstances under which supplemental irrigation may be a viable technology.

A Theoretical Note on Aggregation of Linear Programming Models of Production

Thomas H. Spreen and Takashi Takayama

Linear programming models have been used widely to solve the firm's resource allocation problem. If the model is specified properly, then its solution will give the firm's profit-maximizing levels of output and factor use. The model's ability to predict firm adjustment to changes in a variety of exogenous factors is well-known. It is the model's flexibility and easy application that inevitably led to its use in aggregate studies.

The transition from firm level to regional, industrial, or even national analysis is the source of the aggregation problem. As all firms are not alike, we wish ideally to model every firm and sum up their solution vectors to generate an aggregate solution. The modeling of individual firms of an industry or region of any size, however, is unmanageable, and thus, firms are partitioned into "homogenous" groups. The question becomes how best to form these groups. Studies which have attempted to define empirical rules and practical guidelines include Frick and Andrews, Sheehy and McAlexander, and Buckwell and Hazell. A theoretical curiosity, however, has emanated. Stated simply, do there exist conditions under which a group of firms can be represented by an aggregate model with no loss of information? Day first proposed a set of such conditions upon which subsequent attacks of various sorts have been mounted by Miller, Lee, Marenco, and Paris and Rausser. The purpose of this paper is to reexamine the aggregation issue and offer additional theoretical results.

Issues and Definitions

Consider a set of N firms, each faced with the problem of determining that vector $\mathbf{x}^i$ which

(1) Maximizes $\mathbf{P}^{i\prime}\mathbf{x}^i$

$$\text{subject to } A^i\mathbf{x}^i \leq \mathbf{b}^i, \text{ and}$$
$$\mathbf{x}^i \geq 0 \qquad i = 1, \ldots, N,$$

where $\mathbf{P}^i$ is a nxl vector of prices or net returns, A^i is the mxn technology matrix, and $\mathbf{b}^i$ is the mxl vector of resource availabilities to the ith firm.

Thomas H. Spreen is an assistant professor, Food and Resource Economics Department, University of Florida, and Takashi Takayama is with the Energy Division, Oak Ridge National Laboratory, Tennessee.

Florida Agricultural Experiment Station Journal Series No. 1736. The authors gratefully acknowledge comments by Max Langham and an anonymous reviewer.

Suppose the following specification represents an aggregate model of the N firms:

$$\text{(2)} \qquad \text{Max } \mathbf{P}'\mathbf{x} \text{ subject to } A\mathbf{x} \leq \mathbf{b}, \text{ and } \mathbf{x} \geq 0,$$

which is of the same dimension as the firm models. The aggregation of the firm models given by (1) into an aggregate model given by (2) is said to be totally consistent (Ijiri) if

$$\text{(3)} \qquad x^* = \sum_i \mathbf{x}^{i*},$$

where "*" denotes the optimal solution to each of the models, for any values of $\mathbf{P}^i$ and $\mathbf{b}^i$. Guccione and Oguchi have demonstrated the impossibility of achieving totally consistent aggregation. They assert that the conditions first proposed by Day; namely (a) $A^i = A^j$ (b) $\mathbf{b}^i = \lambda_i\, \mathbf{b}^j$, and ($c$) $\mathbf{P}^i = \gamma_i\, \mathbf{P}^j$ for all i and j, should be considered as restricted domains of the exogenous data. Day's original work also specified a fourth condition which was later shown by Marenco to be redundant.

Previous authors have accepted (3) as the definition of perfect or exact aggregation. Once we restrict ourselves to the case where all firms face the same price vectors, $\mathbf{P}$ ($\mathbf{P}^i = \lambda_i\mathbf{P}^j$ for all i and j says that each firm's price vector differs from all others only by a constant of proportionality. Thus we can assume, without loss of generality, that $\mathbf{P}^i = \mathbf{P}^j = \mathbf{P}$) as implied by condition (c), a more precise definition can be stated. First, let $\mathbf{x}^i(\mathbf{P})$ denote the optimal solution to the ith firm's model given a price vector $\mathbf{P}$.

DEFINITION 1: *Aggregation bias is said to be zero if given any price vector* $\mathbf{P}(\geq 0)$, *the aggregated vector of individual firm optimal output vectors,* $\mathbf{x}^*(\mathbf{P})$, *is exactly the same as the solution* $\mathbf{x}(\mathbf{P})$ *of an aggregate model for the same* $\mathbf{P}$.

DEFINITION 2: *If aggregation bias is zero in the sense of definition 1, for all* $\mathbf{P}(\geq 0)$, *the aggregate model is said to be an exact aggregation model. In terms of norms, one can say that the aggregation is exact if* $d[\mathbf{x}^*(\mathbf{P}), \mathbf{x}(\mathbf{P})] = \sqrt{\sum_j [x^*_j(\mathbf{P}) - x_j(\mathbf{P})]^2} = 0$ *for all* $\mathbf{P} \geq 0$. (The terminology "exact aggregation model" was first used by Miller but since has been adopted by other authors on the subject.)

Note that definition 1 recognizes that the solution **x**(**P**) to a linear programming problem can be viewed as a mapping from price (net revenue) space to commodity space; **P** is mapped to **x**(**P**). Furthermore, this mapping is not one-on-one. This is a critical point. It is not sufficient to show **x**(**P**) = **x***(**P**) for some **P**.

To clarify this point, consider a simple two-firm example which satisfies Day's theorem:

Example 1:

$$\text{Firm 1}\quad \begin{aligned} X_1^1 + X_2^1 &\leq 10 \\ X_1^1 \qquad &\leq 5 \\ X_1^1,\quad X_2^1 &\geq 0 \end{aligned} \qquad \text{Firm 2}\quad \begin{aligned} X_2^2 + X_2^2 &\leq 20 \\ X_1^2 \qquad &\leq 10 \\ X_1^2,\quad X_2^2 &\geq 0. \end{aligned}$$

Using Day's theorem, the aggregate model is

$$\begin{aligned} X_1 + X_2 &\leq 30 \\ X_1 \qquad &\leq 15 \\ X_1,\quad X_2 &\geq 0. \end{aligned}$$

Each individual and aggregate feasibility frontier is depicted in figure 1.

If the price vector is, say, **P** = (1,1/2), the optimum output for the individual firms are B_1 and B_2 with the corresponding aggregate model solution B and aggregation bias is zero. Suppose, however, that the price vector is **P** = (1,1). Individual firms face the problem of implementation because optimal solutions lie on the line segment A_1B_1 for Firm 1 and A_2B_2 for Firm 2. Individual firms, however, have to implement their plans. Assume Firm 1 takes B_1 as its plan and Firm 2 takes A_2. The aggregated implemented plan is C.

The aggregated model is then solved for its optimum plan for **P** = (1,1). The line segment AB is the solution set. Researchers in charge of the aggregated model face uncertainty in attempting to project or pinpoint what would be the realized supply for the region. Not knowing individual plans already implemented, they may choose point B as their projection. But as point B does not correspond with the aggregated solution, point C, "aggregation bias" is nonzero.

The existence of alternative optimal primal solutions for some price vectors precludes the existence of an exact aggregation model. When a price vector **P** is parallel to one of the constraints, the mapping from price space to quantity space defined by the linear programming model is a one-to-many mapping. As pointed out by Ijiri, if the microfunction (the firm linear programming model) is not one-to-one, we cannot hope to find a macrofunction (the aggregate model) which satisfies the conditions of definition 2.

On the other hand, point C, the aggregated output vector, does lie in the solution set of the aggregate problem. Thus, linear programming models can exhibit zero aggregation bias, but not in the sense of definition 1. This leads us to consider the concept proposed by Frick and Andrews which we state as

DEFINITION 3: *Aggregation bias is said to be zero if for any given price vector* **P**(≥0), *the aggregated vector of individual firm optimal output vector, say* **x*** (**P**) *is contained in the solution set* **X**(**P**) *of the aggregate model for the same* **P**.

DEFINITION 4: *If aggregation bias is zero in the sense of definition 3 for all* **P**(≥0), *the aggregate model is said to be a semi-exact aggregation model. In terms of norms, one can say that the aggregation is semi-exact if*

$$\min_{\mathbf{x}(\mathbf{P})\in\mathbf{X}(\mathbf{P})} \{d[\mathbf{x}^*(\mathbf{P}),\mathbf{x}(\mathbf{P})]\} = 0 \qquad \text{for all } \mathbf{P} \geq 0.$$

From our discussion above, we see that linear programming models of production can be semi-exact aggregation models. We summarize our discussion in:

THEOREM 1: *Given a set of N linear programming models and an aggregate model, then the aggregate model cannot satisfy exact aggregation for all price vectors* (**P** ≥ 0), *but may be a semi-exact aggregation model.*

The implication of theorem 1 leads us to ask if linear programming models do not satisfy exact aggregation, are there other functional forms that do satisfy exact aggregation? The answer is yes, as we shall see in the next section.

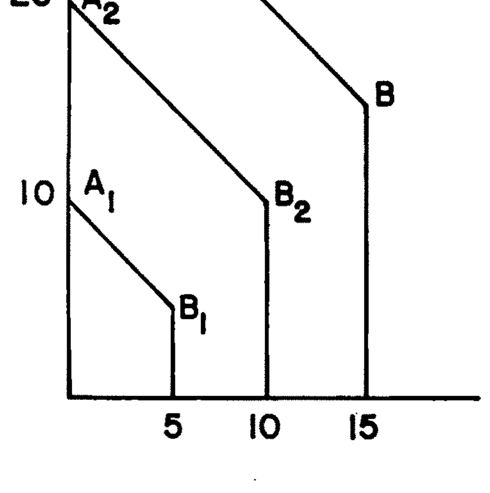

Figure 1. Feasibility frontiers

Exact Aggregation

Linear programming models of production can not satisfy exact aggregation because in linear programming the mapping from price (net revenue) space to commodity space is upper semicontinuous, not continuous. If we restrict ourselves to those constrained optimization models of production in which the mapping is continuous, then exact aggregation is possible.

Consider a set of N individual firms, each with a production efficiency frontier given by $F_i(x) = 0$ where x is k-dimensional, and which satisfy the following conditions.

Condition 1: $F_i(x)$ for all i, are continuous, and at least twice differentiable.

Condition 2: For all $F_i(x) = 0$,

$$\frac{dx_j}{dx_l} \leq 0,$$

for all j and $l \epsilon \{1, 2, \ldots, k\}$ and $j \neq l$, and all $i \epsilon \{1, 2, \ldots, N\}$.

Condition 3: The Hessian of F_i is negative definite everywhere in the nonnegative commodity domain, for all $i = 1, \ldots, N$.

Condition 1 is a smoothness condition for each of N individual production efficiency surfaces. Condition 2 excludes the possibility of discontinuities of the production efficiency frontier such as at B and D shown in figure 2.[1]

Condition 3 guarantees that the individual production efficiency frontiers are smoothly bulging out away from the origin, or the production feasibility set $X_i = \{x|F_i(x) = 0, x \geq 0\}$ forms a strictly convex set. We now state:

THEOREM 2: *If $F_i(x)$ satisfies conditions 1, 2, and 3 for all i, then exact aggregation exists.*

Proofs for this theorem can be found elsewhere (e.g., Takayama and Judge, chap. 15, or Nikaido, chap. 10). An example of the application of this theorem should serve to clarify its meaning.

Example 2: Consider two firms with the following production efficiency frontiers:

$$\text{Firm 1:}\quad 100 - (x_1^1)^2 - 4(x_2^1)^2 = 0$$
$$\text{Firm 2:}\quad 25 - (x_1^2)^2 - 4(x_2^2)^2 = 0.$$

For a given vector $\mathbf{P} = (1,p)$, one can obtain the following optimal outputs for 1 and 2:

$$x_1^1\,(\mathbf{P}) = \frac{10}{\sqrt{1 + (p^2/4)}}$$

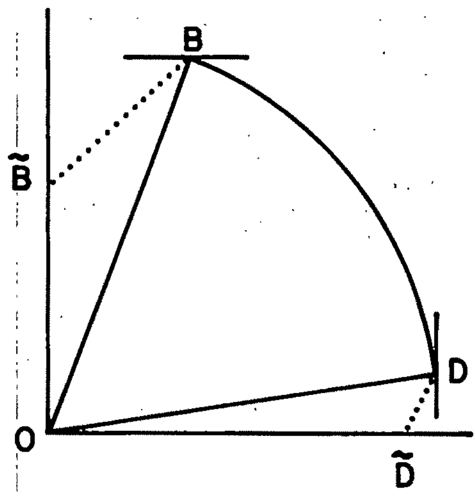

Figure 2. Efficiency frontier

Firm 1

$$x_2^1\,(\mathbf{P}) = \frac{10_p}{\sqrt{1 + (p^2/4)}},$$

$$x_1^2\,(\mathbf{P}) = \frac{5}{\sqrt{1 + (p^2/4)}}$$

Firm 2

$$x_2^2\,(\mathbf{P}) = \frac{5_p}{\sqrt{1 + (p^2/4)}}.$$

By setting $x_1 = x_1^1(\mathbf{P}) + x_1^2(\mathbf{P})$ and $x_2 = x_2^1(\mathbf{P}) + x_2^2(\mathbf{P})$ and eliminating p from x_1 and x_2, the aggregate production efficiency is found to be

$$225 - (x_1)^2 - 4(x_2)^2 = 0.$$

It can be seen the $\mathbf{x}^*(\mathbf{P})$, the sum of the individual firm solutions equal $\mathbf{x}(\mathbf{P})$, the aggregate solution, for all $\mathbf{P}$, and $x(\mathbf{P})$ can be decomposed uniquely into x_k^i (P)'s for $i = 1, 2$, and $k = 1, 2$. Thus "exact aggregation" is clearly exhibited.

The problem is not as easy once one introduces different functional forms for the individual production efficiency frontiers such as

$$\text{Firm 1:}\quad 100 - (x_1^1)^2 - 4(x_2^1)^2 = 0$$
$$\text{Firm 2:}\quad 25 - 4(x_1^2)^2 - (x_2^2) = 0.$$

We challenge the reader to derive, if possible, an analytical expression of the aggregate production efficiency frontier in the form $F(x) = 0$.

The above observations lead us to a more restrictive theorem. First, a definition is required.

DEFINITION 5: *We say that the functions $F^i(x)$, $i = 1, \ldots, N$ are homothetic of the same class if there exist monotonic increasing transformations h^i, such that $h^i[F^i(x)] = G(x)$ for all $i = 1, \ldots, N$ where $G(x)$ is homogenous of degree 1* (Hanoch).

THEOREM 3: *Let $F^i(x) = 0$, $i = 1, \ldots, N$ represent the production efficiency frontiers for a set*

[1] This is due to the fact that the price vector is restricted to be nonnegative; that is, $\mathbf{P} \geq 0$. However, if we allow $\mathbf{P}$ to contain negative components, these discontinuities will disappear as shown by the dotted segments $B\tilde{B}$ and $\tilde{D}D$.

of firms. Assume the $F^i(x)$ satisfy conditions 1–3 above and are homothetic of the same class. Then there exists an aggregate production efficiency frontier, $F(x) = 0$, which is an exact aggregation model of the individual firms.

A proof of this theorem appears in Spreen and Takayama. The homothetic restriction insures that for every price vector **P**, the marginal rate of product transformation for every firm will be identical; thus the optimal output vectors for all firms will differ only by a constant of proportionality, as we observed in example 2.

Semi-Exact Aggregation

Now we turn our attention towards stating a set of sufficient conditions under which linear programming models of production satisfy semi-exact aggregation. In this section, we state and prove a modification of Miller's theorem.

Let us assume that each of the individual firm models satisfy the following condition:

Condition 4: For any price (net revenue) vector **P**, the order and number of binding constraints for each $x^i(\mathbf{P})$, $i = 1, \ldots, N$ are the same. This condition implies two requirements: (a) at each price (net revenue) vector faced by the firms, they all produce exactly the same number and kind of commodities; in other words, the same activities are in solution for every firm, [this is the qualitatively homogenous output vector (*QHOV*) assumption of Miller]; and (b) for each price (net revenue) vector, the constraints which are binding are exactly the same for each firm.

The second requirement of condition 4 excludes the possibility that for each price (net revenue) vector, all firms satisfy the *QHOV* property, but some firms may have one or more resources in disposal, which are binding for other firms. This possibility must be excluded because in the aggregate model, the availabilities of resources to each firm are added together; and thus, in the example above, the impact would be that the surplus of a resource from one firm could be "transferred" to another firm in the aggregate model. The result would be that the aggregated output vector of the individual firm solutions would show less production than the solution from the aggregate model.

THEOREM 4: *Given a set of N firm models as specified in (1) with solution vectors $\mathbf{x}^i(\mathbf{P})$, then sufficient conditions for the aggregate model*

$$\begin{aligned} &\text{Max } P'x \\ &\text{Subject to } Ax < b \\ &\qquad\qquad x \geq 0, \end{aligned}$$

to be a semi-exact aggregation model are that

(i) *$u_i^1 A_i^1 = u_i^2 A_i^2 = \ldots = u_i^N A_i^N = A_i$ for any scalars u_i^j, $0 < u_i^j < \infty$ where A_i^j is the ith row of the jth firm's technology matrix and A_i is the ith row of the aggregate matrix.*

(ii) *$b_i = \sum_{j=1}^{N} b_i^j/u_i^j$ where b_i^j is the availability of resource i to firm j.*

(iii) *The set $x^i = \{x^i | A^i x^i \leq b^i, x^i \geq 0$ is not empty.*

(iv) *The individual firm models satisfy Condition 4.*

Proof: Condition i insures that the technology matrix for each firm is of the same dimension and that each row of A^i is proportional to A^j, for all $i \neq j$. Hence, by dividing each row and right-hand side through by the appropriate constant or proportionality u_j^i, one can assume, without loss of generality, that

$$A^1 = A^2 = \ldots = A^N = A, \text{ and}$$

$$\sum_{i=1}^{N} b^i = b.$$

We differentiate between two cases.

Case 1: Suppose that the price vector **P** is not proportional to any row of A. Then we know that each firm's solution $\mathbf{x}^i(\mathbf{P})$ will be a vertex solution. At this vertex we can identify the activities in solution and the binding constraints. Condition 4 insures that these will be the same for every firm. Let $A_p{}^i$ be that sub-matrix of A^i corresponding to the activities in solution and binding constraints. We know that $A_p{}^i$ is square and nonsingular, and the optimal solution $\mathbf{x}^i(\mathbf{P})$ is given by

$$\mathbf{x}^i(\mathbf{P}) = (A_p{}^i)^{-1}\mathbf{b}_p{}^i,$$

where $\mathbf{b}_p{}^i$ is the vector of right-hand-side values corresponding to the binding constraints. Because $A^i = A$ for all $i = 1, \ldots, N$, then

$$\mathbf{x}^i(\mathbf{P}) = (A_p)^{-1}\mathbf{b}^i.$$

Thus,

$$\begin{aligned} \mathbf{x}^*(\mathbf{P}) &= \sum_{i=1}^{N} \mathbf{x}^i(\mathbf{P}) = \sum_{i=1}^{N} (A_p)^{-1}\mathbf{b}_p{}^i \\ &= (A_p)^{-1} \sum_{i=1}^{N} \mathbf{b}_p{}^i = (A_p)^{-1}\mathbf{b}_p = x(p), \end{aligned}$$

because $\sum_{i=1}^{N} \mathbf{b}^i = b$. Thus when the price vector **P** is not proportional to any row of A,

$$\mathbf{x}^*(\mathbf{P}) = \sum_{i=1}^{N} x^i(\mathbf{P}) = \mathbf{x}(\mathbf{P}).$$

Case 2: Suppose that the price vector **P** is proportional to some row of A, say row s. The optimal solution for each firm will be the set

$$\begin{aligned} \mathbf{x}^i(\mathbf{P}) = (\mathbf{x}^i | A_s{}^i\mathbf{x}^i &= \mathbf{b}_s{}^i \\ \text{and } A_r{}^i\mathbf{x}^i &\leq \mathbf{b}_r{}^i \\ \text{for } r = 1, \ldots, L &\text{ and } r \neq s), \end{aligned}$$

where $A_s{}^i$ denotes row s of technology matrix and $\mathbf{b}_s{}^i$ is the sth entry in the resource vector of the ith firm.

Because $A^i = A$ for all i, then

$$\mathbf{x}^i(\mathbf{P}) = (\mathbf{x} | A_s\mathbf{x}^i = \mathbf{b}_s{}^i \text{ and } A_r\mathbf{x}^i \leq \mathbf{b}_r{}^i \text{ for } r = 1, \ldots, L \text{ and } r \neq s).$$

Define Y to be the set

$$Y = \sum_{i=1}^{N} \mathbf{x}^i(\mathbf{P}) = (\mathbf{x} | A_s\mathbf{x} = \mathbf{b}_s \text{ and } A_r\mathbf{x} \leq \mathbf{b}_r \text{ for } r = 1, \ldots, L \text{ and } r \neq s).$$

However, Y is the solution set to the aggregate, as it can be written as

$$\mathbf{x}(\mathbf{P}) = (\mathbf{x} | A_s\mathbf{x} = \mathbf{b}_s \text{ and } A_r\mathbf{x} \leq \mathbf{b}_r \text{ for } r = 1, \ldots, L\ r \neq s),$$

since $A^i = A$ for all i and $\mathbf{P}$ is proportional to row s of A. Thus $\mathbf{x}^*(\mathbf{P}) = \sum_{i=1}^{N} \mathbf{x}^i(\mathbf{P})$ is contained in the solution set $\mathbf{x}(\mathbf{P})$ for the aggregate problem *QED*.

The example below is given to illustrate Theorem 4.

Example 3: Consider the following individual LP models

$$\text{Firm 1}\quad \begin{array}{l} \text{Max } \mathbf{P}'\mathbf{x} \\ \text{Subject to} \\ \mathbf{x}_1 + 2\mathbf{x}_2 \leq 10 \\ 2\mathbf{x}_1 + \mathbf{x}_2 \leq 10 \\ \mathbf{x}_1, \quad \mathbf{x}_2 \geq 0 \end{array} \qquad \text{Firm 2}\quad \begin{array}{l} \text{Max } \mathbf{P}'\mathbf{x} \\ \text{Subject to} \\ \mathbf{x}_1 + 2\mathbf{x}_2 \leq 15 \\ 2\mathbf{x}_1 + \mathbf{x}_2 \leq 18 \\ \mathbf{x}_1, \quad \mathbf{x}_2 \geq 0. \end{array}$$

The aggregate model is

$$\begin{array}{l} \text{Maximize } \mathbf{P}'\mathbf{x} \\ \text{Subject to} \\ \mathbf{x}_1 + 2\mathbf{x}_2 \leq 25 \\ 2\mathbf{x}_1 + \mathbf{x}_2 \leq 28 \\ \mathbf{x}_1, \quad \mathbf{x}_2 \geq 0. \end{array}$$

Implications for Empirical Problems

Theorem 1 may be named the "impossibility theorem of exact aggregation in linear programming models." We have found that even for a set of firms that satisfy Day's restrictive conditions, an aggregate model cannot be constructed which will be an exact aggregation model for all nonnegative price vectors. Further investigation showed that when we leave the domain of piecewise linear production frontiers (linear programming) and consider only the nonlinear case, exact aggregation is possible, but the aggregate model is analytically difficult to construct unless one imposes further restrictive assumptions. Thus, the possibility of constructing an exact aggregation model in an empirical study is remote.

This conclusion motivates the introduction of the terminology "semi-exact" aggregation. Theorem 4 shows that under still restrictive conditions, a semi-exact aggregation model can be constructed which is of the same dimension as the firm models. Its direct use in empirical studies, however, is limited.

The entire theoretical discussion on aggregation, including this paper, has resulted in little for empirical studies, because all studies presuppose knowledge about every individual firm. As Paris and Rausser noted, the empirical researcher rarely possesses this information. Data are more likely to be available for only a sample of firms or at the aggregate level. Guidance is sought on how best to design a sample to minimize cost, size of the aggregate model, and aggregation bias. We found, in our proof of Theorem 4, that the crucial condition for semi-exact aggregation is that for every price vector, all firms must have the same set of activities in solution. This result is strikingly similar to the aggregation procedure developed by Sheehy and McAlexander. They proposed that firms should be classified on the basis of the most limiting resource for each activity. This criterion is a restatement of the *QHOV* assumption. The implication for empirical studies is that the production patterns of firms is the proper rule of aggregation. Furthermore, cross-section and time-series data is required to examine how firms react to changing price vectors and thus allow researchers to identify those firms whose solution vectors are identical for a given vector, but react quite differently when faced with alternative price vectors.

Consideration of Investment Tax Credit in a Multiperiod Mathematical Programming Model of Farm Growth

Donald W. Reid, Wesley N. Musser, and Neil R. Martin, Jr.

Marginal federal income tax rates on farm firms have been increasing due to higher taxable incomes from increasing farm size, increasing off-farm income of farm families, and inflation. Krause and Shapiro and Barry (p. 29) have noted that agricultural economics research on the impact of these increased taxes is limited. The investment tax credit is a provision of federal income tax law that has received especially limited research attention. Kay and Rister analyzed the impact of this provision on beef cattle replacement, and Chisholm considered its impact on farm machinery decisions. However, the investment tax credit has not been considered in mathematical programming models of farm firm growth in the same manner as other income tax provisions (Vandeputte and Baker, Barry and Willmann). The purpose of this paper is to present a method of incorporating investment tax credit provisions in a multiperiod mathematical programming model. Specific objectives include: review of the theory of capital budgeting in reference to the investment tax credit, consideration of a tax submatrix for a programming model which includes investment tax credit, and presentation of an empirical example.

The Investment Tax Credit and the Theory of Capital Budgeting

In presentation of the theory of capital budgeting, agricultural economists generally follow Hirshleifer in utilization of a net present value framework (Baker, Chisholm, and Hopkin, Barry, Baker). In use of the present value framework, agricultural economists have not been sufficiently aware of its empirical weaknesses when capital rationing limits the capital budget. Hirshleifer noted in this situation that the theoretically correct discount rate was the marginal productivity of financial capital, which cannot be determined until the optimal capital budget is delineated (pp. 452–58). Because the investment of most farm firms is limited to internally generated equity funds plus the debt that can be obtained with this equity given conventional leverage positions, capital rationing could be relevant for many farm situations. Unfortunately, the issue of an empirically relevant discount rate under capital rationing has not been satisfactorily resolved (Baumol and Quandt; Burton and Damon; Mao, pp. 226–40; and Weston and Brigham, pp. 291–304). Beranek notes that one solution is to maximize accumulated wealth at the end of a planning horizon in a mathematical programming framework (p. 139). Boussard has justified this viewpoint in a farm firm growth research context. Weston and Brigham recommend the use of an internal rate-of-return formulation as a reasonable approximation under capital rationing (p. 283); their viewpoint is adopted in this section.

The theory of capital budgeting for a single period with an internal rate-of-return concept can be summarized in three equations:

$$(1) \qquad \sum_t \frac{R_{it}}{(1 + r_i)t} - (C_i - IT_i) = 0,$$

$$(2) \qquad r_i \geq k, \text{ and}$$

$$(3) \qquad \sum_i (C_i - IT_i) \leq B,$$

where R_{it} is future net cash flows from project i in year t, C_i is initial investment cost of project i at $t = 0$, r_i is the internal rate of return of project i, k is the cost of capital for the firm, IT_i is the investment tax credit for project i, and B is the maximum size of the capital budget. Equations (1) and (2) refer to the ith individual project available for investment in a particular period, while equation (3) is concerned with the total investment costs of all projects in this time period. With no financial constraints, B is infinite, and equation (3) is irrelevant to the capital-budgeting process. In this case, a project is included in the capital budget if its r_i, as determined by equation (1), satisfies equation (2).

If B has a finite value, two different cases of capital rationing are possible. In the first, the sum of net investment cost, which is $C_i - IT_i$, for all projects satisfying equation (2) is less than B, and equation (3) is not restrictive. In the second case, investment in all projects in which (2) holds causes (3) to be violated, and capital rationing is effective in restricting investment. The capital budget then includes projects in order of their r_i until (3) becomes restrictive.

Donald W. Reid is a former graduate research assistant and Wesley N. Musser is an associate professor, University of Georgia; Neil R. Martin, Jr., is an associate professor, Auburn University.

An earlier version of this paper was presented as a contributed paper at the annual meeting of the American Agricultural Economics Association, Blacksburg, Virginia, 6–9 August 1978.

S. J. Brannen and two anonymous reviewers made helpful comments on earlier drafts of this paper.

The impact of the investment tax credit on the capital-budgeting process arises from its reduction of net investment cost in (1) and (3). The most apparent effect is that r_i is raised in (1) with an investment tax credit and, therefore, potentially more projects meet (2) than without a credit. If B is nonrestrictive, the number of projects, and therefore the size of the capital budget, will be increased. When B is restrictive, this increase in r_i cannot increase the size of the capital budget but can change its composition if the r_i increase at different rates and the ranking is altered. However, the size of the capital budget also can increase because $(C_i - IT_i)$ is reduced for each project which qualifies for an investment tax credit and more projects can be undertaken.

Methods

In considering the effect of the investment tax credit in the capital-budgeting process, one approach would be to reduce the cost of qualifying investments by the amount of the investment tax credit to reflect net investment cost. However, the investment tax credit can be claimed only if an offsetting income tax liability exists. If low prices or yields result in low or zero tax liability, the investment tax credit has little or no effect on net investment cost. Even in normal years, a large investment in machinery, grain storage facilities, or livestock equipment could result in the investment tax credit exceeding the income tax liability in the year of the investment. Thus, a method of relating investment tax credit to income tax liabilities in both the year of the investment and other years is necessary to assess accurately the effects of the investment tax credit on investment.

A method of incorporating the investment tax credit into a multiperiod mathematical-programming investment model is illustrated in table 1. Part of the income tax activities associated with the nth period, along with production and investment activities linked with the tax activities, are included in this table. Activities *T1n*, *T2n*, . . . , *Tkn*, and rows *TICn* and *PTCn* reflect increasing marginal income tax rates according to Vandeputte and Baker's methods. *MTn* is added to provide for income tax payments on adjusted gross income in the highest tax bracket. *IAn*, *PAn*, and *MAn* are representative investment, production, and marketing activities, respectively, which affect income tax liabilities. Their effects on adjusted gross taxable income are reflected in the *TICn* row—*IAn* results in depreciation equal to A_d, *PAn* has production expenses equal to A_c, and *MAn* has gross revenues of A_r. The remainder of the submatrix involves the investment tax credit. (See also *U.S. Master Tax Guide, 1976*, pp. 431–33).

The basic provision of the investment tax credit—one dollar of tax reduction for each dollar of investment credit—is provided by the *BITCn* activity. Qualifying investment activities, *IAn* provide investment tax credits equal to A_c in the *ITCn* and *ITCYLn* rows. *BITCn*, in turn, uses these investment tax credits with entries in *ITCn* and *ITCYLn*. The tax savings in the subsequent period is reflected in the entry in the *OCA*(n + 1) row for *BITCn*. The amount of base investment tax credit is limited by two other constraints. *EITCLn*, which has entries for investment tax credits and income tax liabilities, limits the investment tax credit to the income tax liability. The base investment tax credit also is limited to a legal maximum B, which was \$25,000 in 1975, with *BITCLn*.

For situations in which the tax liability and investment tax credit earned are greater than the legal maximum, the extra investment tax credit provisions are appropriate. Under 1975 rules, this provision is that one dollar of tax liability results in a half-dollar of tax credit. Activities such as *EITCn* model this provision. The structure of this activity is similar to *BITCn* except that each unit of income tax liability in *EITCLn* allows A_a (.5 in 1975) in investment tax credit in *ITCn*, *ITCYLn*, and *OCA*(n + 1).

In situations in which the current investment tax credit is greater than current income tax liability, the tax credits can be carried back three periods and forward seven years under 1975 rules. These linkages with other periods are provided by *XITCBLnn* and *XITELnn* activities. The carry-back rule is appropriate when investment tax credit is greater than income tax liability in the current period, while income tax liability greater than tax credits existed in previous years. Activity *XITCBLn*(n − 3) which carries current tax credits back three years is an example of the carry-back transfers. The structure of this activity is similar to *BITCn* except that *BITCL*(n − 3) and *EITCL*(n − 3) replace analogous rows for the current period.

If income tax liabilities in carry-back periods are inadequate to exhaust excess earned investment tax credits in the current periods, the carry-forward provisions are appropriate. Activities *XITCBLn*(n + 1), *XITCBLn*(n + 7), and *XITELn*(n + 7) represent carry-forward activities from the current period. These activities use the tax credits provided in the current period, represented by entries in *ITCn* and *ITCYLn*, and supply credits to future periods with entries in *ITC*(n + 1) or *ITC*(n + 2). The cash flows arising from these credits will be reflected in operating capital rows for future periods.

If earned investment tax credits are greater than income tax liabilities in previous periods and less income tax liabilities in the current period, investment tax credits can be transferred forward to the current period. Activities *XITBL*(n − 7)n transfer earned investment from previous periods forward to the current period with entries in *ITC*(n − 7), *ITCYL*(n − 7), and *ITCn*. Activities such as *BITCXn* and *EITCXn* utilize investment tax credit carried forward to the current period and have a

Table 1. Submatrix of Tax Activities in Multiperiod Linear Program

structure similar to *BITCn* and *EITCn* except for no entry in *ITCYLn*.

The transfer activities affect *ITC* and *ITCYL* rows asymmetrically. The function of *ITCYL* rows are to constrain the investment credit either claimed in the current year or transferred to another year to the amount of credit earned from current investments. Thus, activities claiming current credits (*BITCn* and *EITCn*) and activities transferring credits $XITCBLn(n-3)$, $XITCELn(n-3)$, and $XITCn(n+1)$ have entries in *ITCYLn*. The *ITC* rows have the function of constraining tax credits claimed in the current year to that available from current investments and transfers from other years. Thus, transfer activities such as $XITC(n-7)n$ and $XITCn(n+1)$ have negative entries in the $ITC(n-7)$ and *ITCn* rows, respectively. Also, activities that claimed transferred credits, such as *BITCXn* and *EITCXn*, have entries in the *ITCn* row but not the *ITCYLn* row.

A final feature of the investment tax-credit model structure is that small numbers must be added to the entries in the cash row *OCAn*. The magnitude of each entry establishes the priority in which the tax credit is taken while having a negligible effect on cash earned from the credit. For example, the legal priority is established by adding to the usual entry in *OCAn*, .009 for *BITCn*, .007 for *BICXKn*, and .005 for $XITCBLn(n-3)$.

Results

This study utilized a standard, multiperiod, linear programming model which represented a 462-acre farm in the Georgia Piedmont with 164 acres of cropland. The land was fully owned. Resident labor of 2,500 annual hours was available to be utilized either for labor or management of hired labor subject to a managerial constraint of 25,000 hours of hired labor. At the beginning of the planning horizon, a complement of crop machinery for production of corn and soybeans was available. Purchase or rental of additional land was not allowed so that firm expansion was limited to hog enterprises. Starting with zero debt, the firm was allowed to

incur debt during the ten-year period up to 30% of the value of its total assets. A fixed amount of $18,000 consumption withdrawal was assumed for the subject and was augmented at an annual rate of 5% to accommodate inflation. Other prices, costs, and asset values also were subjected to trends with the hog price trends including price cycles (Reid). The objective function of the model was to maximize net worth at the end of the planning horizon. Net worth at the end of the planning horizon reflected value of assets before liquidation (Reid, Musser, Martin).

A summary of the solutions from the model with and without an investment tax credit are presented in table 2. These results indicate that the investment tax credit stimulated firm growth as measured by several criteria (LaDue). In terms of net worth, the solution with an investment tax credit had a higher value in all years than the solution without an investment tax credit. In the final year, net worth was $1,165,809 with a credit and $1,043,945 without. In terms of annual net cash income before taxes, approximated by adjusted gross taxable income, the situation with investment credit was generally higher except for 1975 and 1985. In 1975 the after-tax cash income was higher with an investment tax credit, $30,459 compared to $28,734, and low hog prices resulted in zero taxable income in both situations in 1985 (Reid). In terms of physical output, crop output was the same in both situations. However, more expansion occurred in hog production with the credit; for example, in 1983, 70,767 hundredweight of hogs were sold compared to 50,429 hundredweight without a credit. It can be noted that the largest relative impact of the investment tax credit was on physical production rather than net income or net worth. This result suggests that the investment tax credit benefits consumers of agricultural products more than agricultural producers even at the microlevel.

Table 2. Impact of Investment Tax Credit on Growth Pattern of a Model Farm in the Georgia Piedmont, Selected Years 1975–85

Item	Unit	1975	1980	1983	1985
With investment tax credit:					
Net worth	$	279,321	918,665	1,130,743	1,165,809
Adjusted gross income	$	33,600	199,041	164,839	0
Gross federal taxes	$	7,100	106,454	83,078	0
Investment tax credit	$	3,959	7,066	11,518	2,216
Hired labor	hr.	0	9,874	13,028	0
Market hogs sold	cwt.	3,667	56,396	70,767	1,385
Dual value for long-term security	$	.756	.063	0	.020
Without investment tax credit:					
Net worth	$	274,242	844,779	999,006	1,043,945
Adjusted gross income	$	37,263	176,741	113,402	0
Gross federal tax	$	8,529	91,156	50,017	0
Hired labor	hr.	0	8,585	8,632	0
Market hogs sold	cwt.	3,667	50,429	50,429	1,385
Dual value for long-term debt security	$	.630	.048	0	0

In understanding the process of increased growth with an investment tax credit, it is necessary to consider the investment processes in the two situations. First, the investment process limited expansion in both situations; at maximum hog production during the planning horizon of 70,767 hundredweight of hogs in 1983, hired labor was 13,249 hours, which was well below the managerial constraint level of 25,000 hours. An additional dimension of the investment process is that B in equation (3) is finite because additional equity capital is limited to retained earnings. Furthermore, positive dual values for the long-term debt security restriction in most years indicated that the capital budget constraint was effective in most years. In these years, additional investment with an investment tax credit arises from the influence of lower net investment cost with the tax credit. This lower investment cost is reflected in a greater investment in market hog facilities in 1976–80; the increase in market hog production, which requires these facilities, is greater in each of these years with an investment tax credit.

The effect of the investment tax credit without effective capital rationing is apparent in 1983. In that year, market hog facilities were increased from the 56,396 hundredweight capacity in 1980–82 to 70,767 hundredweight; however, the capacity was maintained at its former level of 50,429 hundredweight without an investment tax credit. Evidently, the existence of the investment tax credit raised the internal rate of return on additional market hog facilities in 1983 to a level above the cost of capital so that equation (2) is met.

The results also allow an evaluation of the necessity to incorporate investment tax credit provisions into the tax submatrix. For this farm situation, investment tax credit was always less than income tax liability except for 1985. In that year, a tax credit of $2,216 was earned on the investment in feeder pig facilities for the expansion of feeder pig production from 13- to 87-sow units. For this year, the model carried $553 of the credit back to 1982 [$XITCBLn(n-3) = 553$] and $1663 back to 1983 [$XITCBLn(n-2) = 1{,}663$]. These activity levels were consistent with the requirement to carry back three years having the highest priority; the income tax liability in 1982 was not sufficient to exhaust the credit, so that the remainder was carried back two years to 1983. It must be stressed that the cash flows generated from the tax credit would be available when income tax returns were filed in this carry-back situation. Thus, sufficient current and carry-back income tax liabilities existed in the model so that investment tax credits could be claimed in the year earned. However, direct adjustment of the cost of capital investments to reflect the investment tax credit would not have reflected the lag of one period between investment and receipt of the tax credit that results from annual tax-filing requirements in farming. The direct method would have accelerated the actual impact of the credit. The same production of 3,667 hundredweight of hogs in the initial period in both situations illustrates the lag in receiving the investment tax credit. Thus, the adjustment of investment costs could have approximated the impact of tax credits in this model but would have overstated its impact on the investment process.

These results concerning inclusion of investment tax credit in multiperiod investment models can be generalized to other farm situations. The condition that sufficient tax liabilities exist in the current and preceding three years, to allow claiming the credit in the current period, does not seem stringent even considering the variability of agricultural production and prices. Only if this condition is likely to be violated would inclusion of investment tax submatrices significantly improve the approximation of the investment process. Such situations include a se-

quence of years with low profits, such as 1985 in the model in this paper, and/or periodic large investments in the model.

A Routing Algorithm Using the Nearest Neighbor Concept: Comment

J. W. Hubbard

Hallberg and Kriebel have demonstrated that utilization of the nearest neighbor concept may save unnecessary backtracking and will minimize distance traveled in servicing product delivery or assembly routes. The Hallberg-Kriebel illustration of an optimum route included one unit of backtracking travel, however, and required sixteen units of travel to service fourteen customers (their fig. 2).

For cases of this kind in which management can influence the layout of the territories to be covered, it easily can be demonstrated that routes can be designed so that nearest neighbor servicing results in no backtracking. All that is required is that the rectangular grid to be serviced have an odd number of blocks in at least one direction. Under the customer location conditions assumed by Hallberg and Kriebel, the number of units of travel will be one greater than the number of customers serviced, if the grid has at least one dimension in which the number of blocks is odd. An optimum route for a grid two blocks in one direction and five blocks in the other direction is illustrated, figure 1. Note that the warehouse could be located at any intersection on the grid without affecting the distance to be traveled. Placing the warehouse at a corner of the grid would permit servicing four similar territories from one warehouse with no backtracking on any route. Grids with an even number of blocks in both directions will require backtracking irrespective of the location of the warehouse. Under the Hallberg-Kriebel assumption as to customer location, an optimum route of travel results in one unit of backtracking on a grid with an even number of blocks in both directions and no backtracking on a grid with an odd number of blocks in at least one direction. For an optimum route, the number of units of travel will be one greater than the number of customers serviced, if the grid has an odd number of blocks in one direction; it will be two greater than the number of customers serviced, if the grid has an even number of blocks in both directions.

Publications

Books Reviewed

Abrahamsen, Martin A. *Cooperative Business Enterprise*. New York: McGraw-Hill Book Co., 1976, xix + 491 pp., price unknown.

This book takes a descriptive-historical-institutional approach to the subject of cooperative enterprise. Most of the information in the book is condensed from a plethora of publications on cooperatives, with limited original analysis conducted by the author. A heavy reliance on Farmer Cooperative Service publications may be explained by the author's many years of service with that agency.

The first nine chapters primarily are devoted to defining cooperatives and to placing their development in historical perspective. Seven definitions of cooperative enterprise from other sources are reviewed, and from these definitions the author derives seven "basic features" of cooperative business enterprise (as distinguished from the general concept of cooperation). Full chapters are devoted to listing types of cooperatives and to charting the historical development of cooperative principles. Chapter 4, which lists many contributors to cooperative theory, carries an orientation common to the entire book: long on history and short on economic analysis. Some recent, rigorous contributions to cooperative thought are mentioned only briefly or are relegated to footnotes (pp. 81–85).

Chapter 10, "Special Legal Problems," contains a useful summary of important court decisions affecting the structure and operations of U.S. agricultural cooperatives. An instructor using this book will need to update the text material with recent court decisions and changes in important legislation, e.g., USDA regulations pertaining to Section 2 of the Capper-Volstead Act.

The author states that there is "much confusion and misunderstanding" about the topic discussed in chapter 11: "Cooperative Taxation;" the information presented in this chapter should help the noninitiated reader better understand this topic. However, less description of legislative and case history of cooperative taxation, and more discussion of contemporary tax issues—including those identified on pp. 241–2—would have strengthened this part of the textbook.

Approximately 30% of the book deals with cooperative management topics, including organization, communication, finance, bargaining, mergers, and liquidation. While the student unexposed to (cooperative or noncooperative) management principles and practices may gain some insight from these chapters, the book patently does not qualify as a "how to" management primer. If management topics are a major emphasis in a course on cooperatives, the instructor would be well-advised to select another text, or to supplement this book heavily with other teaching materials, as recommended in the preface.

The author characterizes his book as "a basic college and university text" to "improve . . . teaching of cooperative enterprise" (p. xv). The reviewer's experience teaching these topics leads him to conclude that the text includes material of interest to lower-division college and high school students of cooperation. However, this book should not be used as the sole reading reference, and its paucity of analytical economic content will limit its usefulness in upper-division and graduate-level university courses.

Cramer, Gail L., and Clarence W. Jensen. *Agricultural Economics and Agribusiness: An Introduction*. New York: John Wiley & Sons, 1979, 440 pp., $18.95.

This textbook is designed to be used in an introductory agricultural economics or agricultural business course. It is well done and deserves serious consideration by teachers wanting an analytical approach to agricultural economics.

The book contains the microeconomic principles included in many introductory courses in an analytical but easy to understand way. After an introduction which gives a student a good overview of American agriculture, it contains a discussion of supply, demand, and price determination; factor-factor, factor-product, and product-product decision making; and a discussion of competitive structure and marketing. These topics would provide the basis for most introductory courses. In addition to this basic material, a wealth of additional topics is covered in the last part of the book, some, but not all of which, will be chosen by teachers for their students depending on their own interests. These topics include discussions of agricultural finance, natural resource use, agricultural price and income policy, international trade, population-food balance, world development, and a particularly interesting section on comparative agricultural systems, focusing on the USSR and China.

This text provides a sound basis for teaching microprinciples in a beginning agricultural economics course. It contains more detail and more topics than most teachers would want to use. However, it is well designed so that the teacher really has no problem in sorting among those things which he chooses to emphasize with his students. The presentations are clear and accurate and the text is refreshingly brief. The text is sprinkled with many

diagrams and tables of factual information, most of which are complete through 1976 and 1977.

Students will like this textbook because it is short, easy to read, particularly clear, and it presents information in an organized way. They will like the summary at the end of each chapter and will appreciate particularly the very brief enumeration of the major points made in each chapter under "chapter highlights." They will like the ready access to a great deal of data describing American agriculture and the wide variety of topics available to them to study.

Teachers will like this textbook because the presentation is clear, concise, and accurate. They will appreciate the wide range of topics in the later part of the book from which to choose to add spice and character to the course.

If this text has a weakness, it is that it puts considerable emphasis on economic theory and the teacher and student looking for ideas to apply today may feel some frustration with it. However, as we teach today, preparing students for the year 2015, it is the theory which will continue to be useful. I agree with the emphasis that the authors have used in this text.

The authors are to be commended for putting together an excellent textbook that can meet the needs of a wide variety of teachers and students of agricultural economics.

Robert W. Taylor
Purdue University

Hayami, Y., in association with M. Kikuchi, P. F. Moya, L. M. Mambo, and E. B. Marciano. ***Anatomy of a Peasant Economy: A Rice Village in the Philippines.*** **Los Banos, Laguna, Philippines: The International Rice Research Institute, 1978, xi + 149 pp., price unknown.**

This intensive case study of a typical rice village in the Philippines deals broadly with the impact of new rice technology and improved irrigation on rural welfare. The study is based on a recognition that the dichotomy of production and investment functions of firms and consumption and savings functions of households typical in the urban sector does not hold in the peasant sector. The economic behavior of the peasant sector must, therefore, be understood in terms of the merging into one within individual peasant households of these four functions. Further, because "to a large extent the village community in developing countries is self-contained" (p. 1), a study of the peasant economy must also involve an examination of the interactions among households within the village, and the role of the village within the overall economy.

To enable an understanding of the complex interactions among economic activities within a household and within a village, data on production, consumption, investment, and transaction activities were collected daily over one year from eleven of ninety-five households residing in Barrio (village) Tubuan, Laguna Province. The data, recorded on seven completely articulated accounts based on the United Nations System of National Accounts, covered current rice, nonrice, and nonagricultural production; income-expenditures; fixed-capital production; capital finance; and transactions. The village social account reflected the aggregate-total of the private economic accounts for individual households in the village, minus transactions and financial claims among households within the village, and plus (*a*) government infrastructure subsidies and (*b*) the stock values of community capital.

The analysis of the village accounts—which in the reviewer's judgment clearly represents the most novel feature of this study—shows that (*a*) the incomes of village dwellers are derived almost exclusively (96%) from agricultural production within the village, with rice dominating by more than four times the other two agricultural enterprises, ducks and pigs; (*b*) of total village output, 58% was paid to village-owned factors, 21% to absentee landlords, 16% to current inputs, and 5% to feed and seed; and (*c*) more than one-half of disposable income was spent on consumer goods from outside the village, about one-third on village-produced consumption, and the balance was saved. The authors tentatively conclude that (*a*) future increases in villager income will have to come from increased rice productivity and/or expanded nonland-based enterprises; (*b*) the substantial supply of unused labor during the off-season months of rice farming could be used to form output-increasing community capital such as irrigation and drainage facilities, fences, and terraces; and (*c*) the current rather heavy reliance of the village on outside consumer goods could be reduced if villagers would expand home garden vegetable production and/or cottage industries.

The authors state that their study "represents an experiment in data collection and documentation for the analysis of the village economy in its whole complexity" (p. 110). *Anatomy of a Peasant Economy* communicates comprehensively the results of this experiment. Its seven accounts and the analysis of the data within them, at the level of both the individual household and the village, are shown clearly. While the accounts omit attention to household chores such as child rearing, cooking, and sweeping—and, therefore, are less complete than what is covered in the *New Household Economics* (deTray)—the authors go beyond conventional treatments in that they base their household and village accounts on a framework of macro-national accounts and deal explicitly with village-level flows of goods and services. Within this perspective, the book will undoubtedly appeal to many micro-oriented members of the research community.

The suggestion that the authors' approach, "if applied to various sites over time, will provide a solid data base for advancing the theory of the

peasant economy as well as for formulating rural and national development policy" (p. 111), in the judgment of the reviewer, however, is considerably more problematic.

In their introduction, the authors cite earlier theoretical and empirical studies of the peasant economy (though they omit attention to Wharton's classical collection of readings on *Subsistence Agriculture and Economic Development*), but indicate that "a serious constraint on the theoretical developments has been a lack of a systematic collection of data amenable to the analysis of the peasant complex" (p. 2). Whereas they proceed to collect a systematic set of apparently relevant data, they make no attempt to utilize their empirical findings to further develop the theory of the peasant economy. Whether their approach can be expected to contribute to the advancement of theory is, therefore, as yet untested.

In their introduction, the authors also state that their planned household-village accounting should provide "the basis for (the more) effective design of rural development programs and national development policy" (p. 2). While on the surface such a proposition has intuitive appeal, further reflection raises some troublesome questions.

Consider first the nature of the illustrative case treated in the book. The village studied is described as a "typical rice village in the Philippines" (p. ix), yet its yields and double-cropping ratio are 65% and 20%, respectively, above the national averages (p. 11), and its population growth rate is almost 40% above the national average (p. 14). The respondents were selected on the basis of their expected ability and willingness to participate in the project, not randomly (p. 4). The some 100 tables and figures in the book, therefore, are based on data from only 11 nonrandomly selected households in a village which in no substantive way can be said to represent all Philippine rice villages.

What can be concluded about national development policies from such a study? Probably not much, as the authors acknowledge in their conclusion: ". . . any generalizations from the data could be hazardous. . . . The tentative policy implications that we have drawn from the experimental study should . . . be taken with great caution" (pp. 110, 11).

What are the possibilities for future studies to overcome the *Anatomy*'s inability to generate policy conclusions? The reviewer concludes that the possibilities are remote. The suggested approach is simply too data-intensive to be relied upon as the primary source of insights for national policy making. While the authors do not indicate the financial resources required to undertake their study, one can imagine that they must have been considerable. Human limitations are probably even more critical. What proportion of Asian rice farmers could be expected to maintain the detailed daily records used in this study? How many researchers would be willing to cope with the massive detail required to manage and supervise the collection and analysis of such a large data-set as that involved in the *Anatomy*? Even if financial and human resources adequate to replicate such a study several times could be mustered, might the payoff to society from using part of these resources in less data-intensive research approaches be greater?

While these questions cannot be answered definitively, the reviewer concludes that the *Anatomy* methodology should be looked upon as but one of several that may be used by policy-oriented social scientists. Within this perspective, he believes that the economic development profession should be indebted to the authors for contributing, via the *Anatomy*, to our analytic capacity to deal with rural development problems.

Wharton, Clifton R., Jr., ed. *Subsistence Agriculture and Economic Development*. Chicago: Aldine Publishing Co., 1969.

Leuthold, Raymond M., ed. *Commodity Markets and Futures Prices*. Chicago, Chicago Mercantile Exchange, 1979, 279 pp., $4.00 paper.

George Croly once asked a reviewer if he had read the book he was reviewing. When the reply was yes, Croly responded, "That's wrong, it creates a prejudice" (Challenge).

This reviewer approached the book at hand with much the same attitude. Two salutary characteristics would seem to make it a worthy work with no further prejudice needed. That is, it stimulates professional discussion by providing a compilation of current research projects, and it explores a subject area which has received too little recent professional attention: the commodity futures markets. The result should not disappoint those wishing to sample a reasonable collection of current research topics and techniques in this subject field.

Eleven papers were selected by the editors and organized into sections on "Price Behavior," "Forward-Pricing Efficiency," "Financial Implications of Hedging," and "Price Relationships." All were drawn from the Fellowships in Futures program started in 1970 by the Chicago Mercantile Exchange. All empirical tests are performed on the commodities traded on that exchange ranging from pork bellies to international money market instruments.

The selection is well-edited, with introductory comments to each major section briefly summarizing the works to follow. In addition, the editor links each paper with the existing literature in the field.

Since the papers were not written with publication in this form in mind, this is an extremely helpful feature.

The works selected for this volume vary tremendously in their sophistication and their focus. They range from specific tests of single behavioral aspects to exploration of a technique which might be used to identify imminent exchange rate revaluations in the international currency market. The selections are too broad for a summary of conclusions here.

A few words may be said, however, about the most interesting portion of the collection: section 4, which deals with price relationships. The three papers included under that heading touch on many fundamental features of the futures markets that have strong policy implications. Although not intended to draw the implications to their fullest, the works deal with the impact of location basis variability on hedging programs, the impact of temporal allocation of seasonal inventories on the inventory adjustment process, and the impact of information flows on market performance. Those following the current policy debates will find this section of particular interest.

If these collected works, and indeed the Fellowships in Futures program are to be faulted, it is in the infrequency with which the fundamental questions pertaining to commodity futures markets are approached. It would be interesting, for example, to see a paper exploring an ongoing monitoring system to identify those contracts no longer functioning efficiently or a paper exploring the role of professional floor traders in establishing new contract markets or new exchanges.

On the whole though, the collected works are well worth reading and reflect favorably on a valuable research program. If the papers in section 4 are an indication of the trend in research sponsored by the CME Fellowships in Futures Committee, their second compilation of research volume should be well worth waiting for.

Challenge, p. 3, July-Aug. 1979.

Witkowski, Edward, and Arnold Wells. *The Economics of Agricultural Production*. Sherman Oaks, Calif.: Alfred Publishing Co., 1979, xi + 231 pp., $14.95.

The authors attempt to provide a textbook for a course in agricultural production economics. They indicate in the preface that most textbooks on the subject are somewhat dated, emphasize institutional material, and obscure the theory. This book is supposed to serve as a teaching tool that emphasizes the method and process of economic decision making.

The book begins with a discussion of the production function, the costs of production, and the revenues from production. This discussion is followed by four chapters on decision making that cover factor-product, factor-factor, and product-product decisions. Finally, the last chapter is devoted to a cursory treatment of linear programming applied to agriculture. Each chapter is designed to provide (*a*) a verbal explanation, (*b*) a tabular example, and (*c*) a graphical depiction of the concept that the authors are attempting to illustrate. Simple questions at the end of each chapter serve as a useful check on the student's understanding of the concept that is presented.

Given the above structure, the book has two major shortcomings. The first pertains to the treatment of the material that is covered and the second to the material that is omitted. Although the expository style is generally adequate, the material contained in the book is wanting. The graphical analyses are repetitious, especially in chapter 6. The tabular examples appear to be based upon hypothetical data, meaningless units of measurement, and unrealistic production practices. These examples would be enhanced by actual experimental data, which would increase the book's credibility with students.

The authors ignore the difficult applications of the theory but indicate in the introduction that the purpose of the book is to aid the agricultural decision maker in a world of increasing complexity. Additional references to more advanced materials, or any other sources, are not provided for the interested student.

The inclusion of a chapter on linear-programming analysis has merit. Yet, the coverage is grossly inadequate. Unless the instructor develops substantial supporting material, this discussion of linear programming is only capable of confusing the student.

The topics that are not covered present a more serious shortcoming in a course concerned with modern commercial agricultural production. More specifically, the book ignores the following topics: (*a*) risk and uncertainty and the application of decision-theoretic analysis, (*b*) acquisition of factors of production and the associated capital investment decisions, (*c*) treatment of limited resource situation and the associated allocation decisions, (*d*) financial management and cash flow accounting, and (*e*) enterprise and partial budgeting analysis. Although avoiding institutional materials is a goal of the authors, they have succeeded in avoiding much additional material that would make the book relevant and interesting to students.

In summary, the book avoids many topics relevant to an undergraduate course in agricultural production economics and does not provide appropriate and concise illustrations for the topics that are covered. Thus the quest for a suitable text must continue.

JOURNAL OF

AGRICULTURAL ECONOMICS

VOL. XXXI, NO. 1 JANUARY 1980

CONTENTS

Published thrice yearly; annual subscription £7.50p.
Editor: R. F. Lord, The Edinburgh School of Agriculture, West Mains Road, EDINBURGH, EH9 3JG, Scotland.
Treasurer: Ian G. Reid, Centre for European Agricultural Studies, Wye College, ASHFORD, Kent, TN25 5AH,
to whom all enquiries regarding membership of the Society and orders for Journals should be sent.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches. On the left margin, number the lines consecutively.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.

Volume 62 Number 2

May 1980

AAEA Annual Meeting
University of Illinois
Champaign-Urbana
27-30 July 1980

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

ISSN 0002-9092

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

Beginning 1 May, all manuscripts and editorial correspondence, except as noted below, should be addressed to the new editor, James P. Houck, Department of Agricultural and Applied Economics, University of Minnesota, St. Paul, MN 55101

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the new book review editor Ronald A. Schrimper, Department of Economics and Business, North Carolina State University, Raleigh, NC 27607

Beekeeping, Pollination, and Externalities in California Agriculture

John W. Siebert

Pesticide-induced beekills cost California beekeepers almost $1 million in 1975. California almond growers depend on bees for crop pollination and thus lost approximately $200,000 from beekills during this same year. A partial equilibrium framework is employed to calculate the marginal revenue product of a bee colony to the beekeeper and the marginal value product of a bee colony employed by an almond grower. The issue of bee protection is addressed in the context of the Tulare County citrus nectary. It is found that substantial net gains in total income were realized from the establishment of a bee protection area.

Key words: almonds, citrus, cost-benefit analysis, externalities, honeybees, pesticides, pollination.

California beekeepers earn a living through the production and sale of the multiple apiary products: honey, pollination service, and bees. These products are produced through a reliance on both commercial crops and natural forage. A serious problem arises when pesticide-induced beekills occur. Both beekeepers and growers of crops dependent on bees for pollination suffer financial losses. This article investigates such externalities from the viewpoints of the beekeeper who needs crops for honey production, the grower who needs bees for pollination, and the grower who uses pesticides and, in so doing, kills bees. Because of both the intractable nature of externalities and of weaknesses in certain data, the results obtained in this study should be considered exploratory.

To investigate growers who require pollination, almonds were selected because they have the highest total revenue of all California crops dependent on bees. Such revenue equalled $115 million in 1975. To investigate growers who use pesticides and, in so doing kill bees, citrus was selected because (*a*) bees are dependent upon citrus nectar for honey production, and (*b*) substantial beekills have occurred in citrus groves. With the exception of tangerines and tangelos, most citrus is not dependent on bees for pollination.

In what follows, a partial equilibrium framework will be developed and used to obtain estimates as to the external cost which pesticide-induced beekills impose upon beekeepers and upon almond growers. Then attention will be turned to the role of property rights. Recent property right reassignments in the Tulare County citrus nectary will be investigated through a cost-benefit framework similar to many of the empirical works surveyed by Mann. While almond growers and citrus growers face quite different production problems, the plight of the beekeeper serves as both the link between these problems and the reason for the focus of the study.

Background

Pesticides kill an 11% average of California's bees each year (Siebert). Still, there can be little doubt as to the importance of beekeeping in California. In 1975, more than $411 million dollars worth of crops depended on bees for pollination, while the beekeeping industry itself produced output valued at $22 million.

Economists (Meade, Cheung, and Johnson) have given substantial attention to the problem of bees and externalities. However, such

John W. Siebert is an associate professor in the Department of Agricultural Economics, Purdue University.

This paper is the result of research sponsored by the California Agricultural Experiment Station in the Department of Agricultural and Resource Economics at the University of California-Berkeley.

The author would like to thank Peter Berck, David Bessler, Richard Just, Richard Norgaard, David Zilberman, and two anonymous referees for their suggestions and comments. Purdue Journal Paper No. 7664.

work has not focused on pesticide problems. Instead, it has examined the market for honey forage land and/or pollination services when information may be imperfect. Cheung (p. 30) held that society's relevant beekill issue is "whether the gain from using the pesticide is greater than the associated loss of bees, in total and at the margin." However, he did not estimate the cost which pesticide externalities impose upon beekeepers or upon growers who use bees for pollination. Cheung did cite examples wherein beekeepers and growers have cooperated to reduce bee deaths. But the detailed specification of property rights was taken to be unimportant in determining the externality.

The Analytical Framework

Following the framework set out by Castle, consider a beekeeper with the revenue function $R = R(\bar{Z}, Z_2)$, where R is the total revenue from the sale of all apiary outputs, $\bar{Z}$ denotes a vector of inputs, and Z_2 denotes the beekeeper's peak colonies ($\partial R/\partial Z_2 > 0$). Also consider the production function of an almond grower who uses bees for pollination, $Y = Y(\bar{X}, X_3)$, where $\bar{X}$ denotes a vector of inputs to almond production and X_3 denotes the almond grower's use of bees for pollination ($\partial Y/\partial X_3 > 0$). Finally, consider the production function of a grower who does not need bees for pollination, $S = S(W_1, W_2)$, where W_1 denotes the use of pesticides and W_2 is another input. When pesticides are used, nearby bees often die: $\partial Z_2/\partial W_1 < 0$, and $\partial X_3/\partial W_1 < 0$.

The externalities analyzed in this article are the beekeeper-pesticide user externality, $(\partial R/\partial Z_2)(\partial Z_2/\partial W_1)$, and the pollination user-pesticide user externality, $(\partial Y/\partial X_3)(\partial X_3/\partial W_1)$. If these two externality effects are to be at efficient levels in terms of maximum social product; then, aside from the satisfaction of the total condition, it must be the case that the aggregate marginal benefit of pest control just equals the aggregate marginal cost to the pesticide users themselves plus the aggregate marginal external costs to beekeepers and those growers dependent on bees for pollination. While an estimate of the efficient level of pesticide use is beyond the scope of the present study, estimates of $\Sigma[(\partial R/\partial Z_2)(\partial Z_2/\partial W_1)]$ as summed over all beekeepers and $\Sigma[(\partial Y/\partial X_3)(\partial X_3/\partial W_1)]$ as summed over all growers are presented.

A Beekeeping Production Function

California beekeepers earn revenue from the sale of five different products: honey, beeswax, pollination, queen bees, and packaged bees. Although honey and beeswax are fixed coefficient outputs in relation to each other, when given a suitable environment the beekeeper can choose independently the relative quantities of the other outputs. To produce honey, the bees require access to plants with heavy nectar flows. To produce pollination, the bees must visit plant flowers and in so doing transfer pollen, thus causing those plants to bear more fruit than they would have otherwise. To produce queens, a laboratory-like process is followed whereby several queens are raised simultaneously. Finally, packaged bees (field bees raised by one beekeeper and sold to another) are produced by providing colonies with early season access to plant flowers with heavy pollen content.

The primary input of the beekeeping firm is the bee colony itself. Other significant inputs include labor, transportation equipment, bee food, and honey-processing facilities. Labor is important because (*a*) bee colonies grow and thus need frequent attention to insure that overcrowding does not exist, and (*b*) both transportation and honey extraction require labor. All beekeepers need transportation for their bees because no one small area contains a wide enough variety of forage for the entire year. Bee food and/or pasture are necessary to insure that the bees do not starve. The honey house and processing equipment are required to extract and package the honey crop.

To estimate a beekeeping production function, 1968 cross-section data on forty-eight California firms were obtained from Reed and Schneider (1976). Using these data the following Cobb-Douglas revenue function was estimated:[1]

$$R = \beta_0 Z_1^{\beta_1} Z_2^{\beta_2} Z_3^{\beta_3} e^u, \tag{1}$$

where R is the total revenue of the beekeeping firm from the sale of all outputs, Z_1 is the number of spring colonies, Z_2 is the number of peak colonies, Z_3 is the labor in man hours, and $u \sim n(0, \sigma^2)$. The results for log-linear estimation of (1) are shown in table 1.

It should be recognized that the revenue

[1] Managerial information for these beekeepers was not available; hence, the coefficient estimates may be biased. Klein (p. 212) discussed the assumptions which underlie specifications of this nature.

Table 1. OLS Estimation of a Cobb-Douglas Revenue Function for Beekeeping

$$\ln R = \underset{(0.5726)}{2.2272} + \underset{(0.1632)}{0.4837} \ln(Z_1) + \underset{(0.1236)}{0.3639} \ln(Z_2) + \underset{(0.1025)}{0.2860} \ln(Z_3)$$

$R^2 = 0.8552$ SSR $= 6.1343$

$n = 48$

Note: R is defined with 1975 prices while all output and input quantities are based on 1968 cross-section data. This was done because (*a*) only 1968 data were available and (*b*) the policy analysis which follows is for 1975. It is true that the above estimate for β_2 lies within the 95% confidence interval for β_2 when 1968 prices are used. However, some problems still exist in that 1968 was a poor year for honey production. The figures in parentheses are standard errors.

function shown in (1) does not conform with basic microeconomic theory. Such theory (Henderson and Quandt, p. 89) explains multiple output production as the result of profit maximization constrained by a concave production possibility frontier (*PPF*). Therefore, before estimating (1), Hasenkamp's Constant Elasticity of Transformation—Cobb-Douglas production function was estimated. However, the resultant *PPF* was convex to the origin, thus precluding the derivation of any supply or demand curves. Hence, the revenue function, rather than a multiproduct production function, was used to determine the financial effect of bee deaths.[2]

Beekeeping under Externality

Because most beekills occur in the summer months when the colony population is at its peak, the 1975 externality impact of pesticides on the entire beekeeping industry can be calculated in terms of the value of profit foregone,

$$K = \sum_{i=1}^{N} \left[\int_{Z_{i2}^0}^{Z_{i2}^1} (\partial R_i/\partial Z_{i2} + \partial C_i/\partial Z_{i2})\, dZ_{i2} \right],$$

where R_i is the total revenue earned by beekeeper i, C_i is beekeeper i's cost of replacing dead colonies, Z_{i2}^0 is the initial number of peak colonies owned by beekeeper i before pesticide damage, Z_{i2}^1 is the number after pesticide damage, and N is the total number of beekeepers in the California beekeeping industry. To facilitate estimation, K is simplified to

$$(2) \quad \hat{K} = [\text{mean } (\partial R_i/\partial Z_{i2}) + RCPC] \cdot (\Delta Z_2),$$

where mean $(\partial R_i/\partial Z_{i2}) = \dfrac{1}{48} \sum_{i=1}^{48} \left(\dfrac{\hat{\beta}_2 R_i}{Z_{i2}} \right) =$ \$10.78 is the change in total revenue with respect to a change in colony numbers. This figure is calculated over the sample of forty-eight beekeepers using the regression results in table 1. *RCPC* is the replacement cost per colony, which is \$20.38. This cost is set equal to the price of a queen bee (\$4.92) plus the cost of two pounds of bees (\$10.46) plus the labor cost for hive reconditioning (\$5.00). Finally, ΔZ_2 denotes total statewide bee deaths, or 31,000 colonies in 1975. The resultant estimate of damages is thus, $\hat{K} = \$31.16 \times 31{,}000 = \$965{,}960$.

An Almond Production Function

Almonds bloom in February and March, earlier than any other crop which requires bees for pollination. Cold, short days sharply reduce both the hours of bee flight and the receptiveness of flowers to pollination. To insure successful pollination, the employment of large and vigorous bee colonies is necessary (Sheesley and Poduska). Should colony damage occur during pollination, most likely from a neighbor's pesticide use, a substantial reduction in yield would result.

Because almonds are a perennial crop, rather than an annual crop, age of the plant is a crucial variable in determining yield. French and Matthews study of asparagus production is an excellent source of information on the procedures for estimating perennial crop production functions. To predict yields, the authors rely heavily on the acreage of plant age cohorts as independent variables. Unfortunately, plant age data were only available at the macro (county) level, while pollination data were only available at the micro (firm) level in cross-section data. Thus, to estimate the marginal productivity of bees, 1974 cross-section data on 117 almond growers were used. These data were provided by Pope of the University of California-Davis.

[2] It is felt that the convex *PPF* was obtained because most of the beekeepers in the sample (37 out of 48) did not produce all three outputs. In regard to the revenue function, analysis of variance on county data showed that average revenue per colony did not differ among Northern, Central, and Southern California beekeepers.

Consider then a cross-section production function for almonds, $Y = f(X_1 \ldots X_6)$, where Y is the total output of almonds in hundredweights, X_1 is total pruning expenditure in dollars, X_2 is total acreage, X_3 is total pollination in colonies, X_4 is total cultivation in dollars, X_5 is total fertilization expenditure in dollars, and X_6 is total pest control expenditure in dollars. Note that information on tree age was not available. Instead, pruning expenditure is used as a proxy variable for age because almond trees require progressively more pruning as age increases. Information on water expenditure was available. However, this information was not used because water charges and rainfall levels fluctuate widely throughout the state, thus the quantity of water used by a producer was unknown.

The following Cobb-Douglas production function was estimated using X_1 through X_6 as defined above,

$$Y = \beta_0 \left(\prod_{i=1}^{6} X_i^{\beta_i} \right) e^u,$$

where $u \sim N(0,\sigma^2)$. Table 2 shows the estimation results for three different Cobb-Douglas function models. Although there exists no truly sound method for deleting variables from regression models (Debertin and Freund), model 1 is suspect because of the abnormally high coefficient on pesticides (X_6). Likewise, model 2 is suspect because of the abnormally high coefficient on fertilizer (X_5). Because both X_5 and X_6 are highly correlated with acreage (X_2), perhaps such variables should be deleted because they are picking up the effect of acreage on production, as well as their own positive effects. Assuming one can justify such variable removal, model 3 appears reasonable in that X_2 finally has assumed its rightful importance.

In comparing these three models, we see that the coefficient on pollination varies from 0.0864 to 0.2602. Because it is difficult to say which of these estimates is more accurate, both values will be used.

Almond Production under Externality

The externality impact of pesticides on the almond industry now can be calculated in terms of the value of profit forgone due to bee deaths,

$$L = \sum_{i=1}^{N} \left[P \int_{X_{i3}0}^{X_{i3}1} (\partial Y_i / \partial X_{i3}) \cdot dX_{i3} \right]$$

where P is the price of almonds per hun-

Note: The figures in parentheses are standard errors.

dredweight (cwt), Y_i is the yield (in cwts.) realized by grower i, X_{i3}^0 is the number of colonies initially employed by grower i, X_{i3}^1 is the number after externality, and N is the total number of growers in the California almond industry. For ease of estimation, L was simplified to

$$\hat{L} = P\,[\text{mean }(\partial Y_i/\partial X_{i3})]\,\Delta X_3,$$

where P is the price of almonds per cwt. = \$40,00, mean $(\partial Y_i/\partial X_{i3})$ = 0.89 cwts. for model 1 and 2.69 cwts. for model 3, and ΔX_3 is a statewide estimate of the number of colonies killed while pollinating almonds equals 3,300. Performing the indicated multiplication it can be seen that $\hat{L}$ lies between \$117,480 and \$355,080.

The Burden of the Externality

As shown above, it was calculated that beekeepers lost approximately \$965,960 from pesticide damage while almond growers lost between \$117,480 and \$355,080. An interpretation of the actual meaning of these figures is important but difficult. First, consider beekeepers. Judging from their recent profitability (Reed and Horel [1976] estimate a 1975 return on total assets equal to negative 1.16%) it is at least likely that bee damage does not improve profitability.

Beekeepers can, and do, receive compensation for bee damage through the U.S. Department of Agriculture's Beekeeper Indemnity Payment Program. So long as the beekeeper can prove he was not at fault and so long as the correct government forms have been completed—the compensation will be paid at about 75% of the value lost. Beekeeper participation in the program is low because documentation of claims is difficult (Morse). For 1975 California beekeepers received \$362,285 in compensation which should be subtracted from the above loss estimate. Reimbursement occurs only once a year in April and pertains to the previous year's claims. Johnson (p. 47) points out that the indemnity program lessens incentives for beekeepers and growers to protect bees.

In contrast, the almond industry has exhibited healthy profitability. Reed and Horel (1975) calculate that the 1973 return on total assets was 18.81%. Even so, the externality is undoubtedly a costly problem to those almond growers who experience a large bee kill. It also should be noted that because almonds are an excellent source of pollen, California beekeepers and out of state beekeepers compete for almond pollination sites. Hence, losses of bees probably have not increased the price almond growers must pay for pollination.

Costs and Benefits of Bee Protection

In his 1971 survey article entitled "Honeybees, Pesticides, and the Law" Happ (p. 129) found that, "every case decided so far by the courts concerning the poisoning of honeybees has relied on the basic concept that no liability would exist if the honeybees died as a result of contact with the poison when they were operating beyond the confines of their owner's apiary." Two reasons explain why pesticide users traditionally have been assigned property rights to the land upon which bees forage without paying rent. First, while it is easy to determine if pesticides were the cause of bee deaths, it is difficult to determine the location of such pesticide contamination. Unless evidence actually shows that the apiary itself was sprayed, it is assumed that the foraging bees contacted pesticides away from the apiary and transported the contamination back to the hive. Note that in pollination contracts beekeepers receive protective guarantees regarding the grower's use of pesticides. Thus when damage occurs during pollination, it usually is caused by bees traveling to neighboring fields.

The second reason pesticide users hold the property right is that the products of beekeepers and growers who rely on bees account for only 5% of California's agricultural revenue. Here political power (as indicated by such revenue) plays a key role. The political decision as to which party is liable for damages seems to have been made in an analogous manner to that described by Samuels in his article on cedar rust and apple trees.

The Case of Tulare County Citrus

While most citrus varieties do not require bees for pollination, bees do obtain substantial nectar yields from citrus blossoms. Therefore, many beekeepers annually transport their bees to citrus regions in order to take advantage of this honey flow. A beekeeper will sometimes give the grower a payment in honey in order to

locate on that grower's property. More often, however, the beekeeper will locate on adjacent property to avoid paying an apiary rent. The bees still realize a substantial nectar yield simply by trespassing.

During the 1974 citrus bloom, citrus cutworm infested the Tulare County groves, thereby forcing growers to spray. The result was a substantial bee kill and drastically reduced honey yields. A survey by the Tulare County Agricultural Commissioner indicated that every colony in the county was adversely affected to some degree.[3] Without waiting another season to see if beekeepers and growers could solve this problem by themselves, in 1975 the commissioner began a rigorous program of forcing pesticide applicators to alter their treatment programs so as to protect bees.

In order to both adhere to the commissioner's regulations and to control the cutworm, most growers switched from daytime applications of Sevin and Guthion to night and early morning applications of Lannate. Such a practice has not adversely affected yields, but it has raised costs an average of $8 per treated acre. Because (*a*) Tulare citrus land has averaged 91,100 acres for the period 1974–78 and (*b*) since 1974, approximately 35% of this acreage has been worm-infested, the citrus industry's bee protection costs have averaged $255,080 per year. In regard to beekeepers, the costs which citrus pesticide damage imposed for the period 1974–78 are shown in table 3.

One can now estimate the net change in incomes arising from the adoption of a liability law which protects bees. First calculate the average amount beekeepers save each year from protection. This can be done by taking the difference between their 1974 loss (when bees were unprotected) and the yearly average of their 1975–78 losses (when bees were protected)

1974 beekeepers' losses	= $1,324,650
Average 1975–78 beekeepers' loss	= $ 346,760
Average annual amount beekeepers' saved	= $ 977,890

Then, taking the difference between the average amount beekeepers save and the average amount growers spend obtains an estimate of the net gain from pesticide regulation enforcement

Average annual amount beekeepers' save	= $ $977,890
Average annual amount growers spend	= $ 255,080
Average annual net gain	= $ 722,810.

Hence, the Tulare County regulations do generate a positive net gain.[4]

Suppose policy makers decide to reassign property rights in favor of the citrus grower. This could be accomplished through a program whereby beekeepers pay a tax to the commissioner in order to locate their bees in Tulare during citrus bloom. The intent of the

[3] The indirect effect of this loss on almond pollination is not thought to be significant because so many beekeepers compete for almond pollination sites.

[4] The number of beekeepers who received government indemnification for this damage is not known. However, indemnification is thought to be paid in about one out of every four cases of damage (Morse). Note that (*a*) because indemnification reduces the beekeeper's loss, it consequently reduces the beekeeper's gain from Tulare bee protection. Also, (*b*) because such indemnification is paid with public funds, the Tulare program may increase the welfare of unrelated U.S. taxpayers since less indemnification is required.

Table 3. Bee Colony Damage and Cost Estimates, Tulare County

		Colony Damage and Cost						
		Killed		Severe		Moderate		
Year	Total Number of Colonies	Number	Cost	Number	Cost	Number	Cost	Total Cost of Damage
			$		$		-----	$ -----
1974	150,000	0	0	7,500	155,775	112,500	1,168,875	1,324,650
1975	150,000	0	0	1,500	31,155	67,500	701,325	732,480
1976	150,000	0	0	700	14,539	12,000	124,680	139,219
1977	275,000	0	0	0	0	48,400	502,876	502,876
1978	121,085	0	0	0	0	1,200	12,468	12,468

Source: Tulare County Agricultural Commissioner; costs are based on the estimates in equation (2), and each killed colony is valued at $31.16. Using an established industry rule of thumb, severely and moderately damaged colonies are valued at two-thirds and one-third this amount, respectively.

tax would be to compensate growers who have adopted special pest treatment techniques solely to protect bees. The program could use the same personnel who presently enforce the bee protection area. If the bee population was 169,217 colonies (the average 1974–78 level) and the tax was intended to raise the extra $255,080 growers spend, it would equal $1.51 per colony.

This plan would accomplish two important results. First, it would bring a profitable cooperation between beekeepers and growers because growers would benefit financially (or at least not lose) from the presence of bees. Such cooperation could let bees locate in the growers' fields and also let beekeepers place their hives at higher densities. Second, it would defuse a lot of hostility between beekeepers and growers. Those who subscribe to the Coasian point of view may feel that the best solution in terms of total income would be to abolish all bee protection measures. While this may be true in the long run, today such a change cannot receive serious consideration in light of the successful performance of the existing protection arrangement.

Conclusion

It has been shown that beekeepers suffer substantial financial losses when their bees are damaged by pesticides. For 1975, losses equaled $965,960, or more than 4% of California beekeepers' annual income. In contrast, almond growers, who must depend on bees for pollination, suffer much less from beekills, with losses equaling at most 0.3% of total income. Such a different relative impact results because many colonies are damaged, but few are damaged while pollinating almonds. Furthermore, the pollination rents almond growers pay are kept low because both California and out-of-state beekeepers compete for almond sites.

In examining the case of Tulare County citrus, it has been shown that substantial net financial benefits ($722,810 annually) arise from mandatory requirements to protect bees. However, should policy makers feel it is unfair to so restrict growers without providing compensation, an alternative plan has been outlined. This would involve taxing all bee colonies located in Tulare County during citrus bloom. The proceeds of the tax would compensate growers who, in turn, would still be required to protect bees.

Optimal Stochastic Control of U.S. Wheat Stocks and Exports

Oscar R. Burt, Won W. Koo, and Norman J. Dudley

A stochastic dynamic programming model was developed to estimate optimal strategies for U.S. wheat reserves policy using the results of an econometric model which reflects the complex dynamics of supply response. Empirical results indicated that U.S. producers are the beneficiaries of a wheat storage program, while domestic and foreign consumers are relatively small and large losers, respectively. Another result is that wheat storage capacity in excess of 2 billion bushels is difficult to justify economically.

Key words: buffer stocks, commodity storage, dynamic programming, grain reserves, price stabilization, wheat.

The tendency noted by Thurow for economists to concentrate their research efforts on popular problems and issues of the times is exemplified by the recent flood of research in agricultural economics—both theoretical and empirical—on commodity storage questions. The theoretical research has focused on generalizations of the questions raised in the early work of Waugh, Oi, and Massell; the major contribution in methodological approach was made by Turnovsky (1976). The empirical work has used simulation, e.g., Reutlinger; Sharples, Walker, Slaughter; and Zwart and Meilke; and several control theory or dynamic programming applications have been made (Arzac, Taylor and Talpaz, Gustafson, Johnson and Sumner, and Cochrane and Danin).

Much of the recent theoretical work places heavy demands on empirical measurement of supply and demand relationships (see Just and Hallam for a brief survey). Although consistently confirming that price stabilization improves global welfare, the theoretical results indicate that the distribution of benefits from storage between producers and consumers is related critically to the curvature of the demand and supply functions, as well as to the way in which stochastic disturbances act on the relationships, additive versus multiplicative (Turnovsky 1976). We must also recognize that the distribution of benefits is dependent on institutional arrangements in the international trade arena (Just et al.). The available data for distinguishing between various functional forms or stochastic specifications on the disturbances are limited. The recent empirical research of Just and Hallam reinforces our opinion that the statistical significance needed for the necessary discernment is weak.

Most of the theoretical work considers only the two polar cases of no storage versus sufficient storage to stabilize price completely (Turnovsky 1974, 1976, and Just et al.). Storage costs are assumed to be zero and discounting is not used. Quite apart from the loss of production and consumption adjustments in response to price signals, complete stabilization of prices will not be economically optimal with either discounting or positive storage costs. The trade-off created by storage costs is rather obvious, but some price variation should exist under discounting, even with zero storage costs, because the buffer stock required to stabilize prices completely has an opportunity cost.

In a dynamic optimization model, where short-run information on production and consumption is incorporated into the stochastic sequential decision framework, it would seem that benefits are more likely to accrue to both consumers and producers than has been found to be the case for the simplified theoretical

models. An optimization model which uses the expected sum of producers' and consumers' surpluses as a criterion does give weight to each group, while a simple comparison between no storage and sufficient storage to remove all price variability (using the same criterion) easily could be a comparison of two relatively bad extremes, neither worth serious consideration.

Although the foregoing casts doubt on the relevance of the theoretical results for empirical commodity storage models, it is only prudent to perform sensitivity analysis in our empirical studies. If the capability of econometric methodology and our weak data base is inadequate to discern the curvature of demand and supply functions, or to discern between additive versus multiplicative disturbance terms, our only recourse is to use a good deal of sensitivity analysis and hope that negative results are not forthcoming.

This study of the U.S. wheat industry was an attempt to develop the methodology for a stochastic dynamic optimization model which would fully exploit short-run information on supply response and demand for U.S. wheat exports. A detailed econometric study was undertaken to estimate wheat supply response, and a Box-Jenkins type time-series analysis was done on annual export prices at the Gulf ports to provide short-run information on export demand. The optimization model is that of Markov process dynamic programming (Howard) with an adaptation to exploit extra information beyond that contained in the formal state variables.

The Econometric Model

Wheat supply response was factored into acreage and yield equations, which makes quantity produced the product of these two equations. Demand was divided into four components: (*a*) domestic food, (*b*) domestic livestock feed, (*c*) seed, and (*d*) exports.

Wheat Acreage Equation

Because of complexities in government programs before 1961, the sample of time-series data used was for the crop years 1960/61 to 1975/76; the last year of the crop-year is the year wheat was harvested. Government policy variables were patterned after the research of Garst and Miller, except that acreages going into the diversion and set-aside programs were thought by the authors to be jointly dependent with acreage seeded to wheat. These acreage variables were replaced by dummy variables to indicate the years in which the programs were operative, but the set-aside dummy did not show statistical significance.

After adjustment of policy variables to no government programs, the wheat acreage equation was

$$
\begin{aligned}
(1)\quad A_t = {} & -20{,}881 + \underset{(20.2)}{12{,}232\,FGP_t} + \underset{(22.5)}{6553SP_{t-1}} \\
& + \underset{(5.3)}{1886P_{t-1}} + \underset{(67.8)}{15{,}138P_{t-2}} + \underset{(15.9)}{.3733A_{t-1}} \\
& - \underset{(17.1)}{.4288A_{t-2}} + \underset{(21.1)}{.4857A_{t-3}} + u_t,
\end{aligned}
$$

$$
(2)\qquad u_t = \underset{(16.9)}{-.921u_{t-1}} + \epsilon_t,
$$

$$
\bar{R}^2 = .9999 \text{ and } s = 74,^{1}
$$

where FGP is the feed grain price index; A is acres seeded in thousands; SP is September price the fall before harvest; P is crop-year (1 July to 30 June) average price, and u is the stochastic disturbance term. Approximate t-ratios (absolute values) are in parentheses below the respective parameter estimates. Prices include government subsidies on a per bushel basis and are deflated by the index of prices paid by farmers for production items. (All deflators of the study are 1967 base.) September price is average market price received by farmers plus the average subsidy per bushel during the crop year in which September falls. Short- and long-run elasticities at sample means are 0.22 and 1.44, respectively.

The weakest aspect of the acreage equation was only two degrees of freedom, but it sequentially predicted one year ahead beyond the sample with much better precision than the best alternative model. Because the decision was made to use (1) in the storage model, two more years of data have become available and the one year ahead predictions have been within 4% error of the mean of 60 million acres, but there is some evidence of underestimation because prices have abruptly declined.

Individual coefficients on lagged prices and acreages in (1) cannot be interpreted directly, but must be taken jointly as a rational lag approximation to the underlying lag distribu-

[1] $\bar{R}^2$ is the adjusted coefficient of determination which includes the explanatory value of serial correlation, and s is the standard error of the estimate.

tion on wheat prices (Griliches). The lag distribution has a somewhat irregular pattern which probably is caused by the heavy influence of summer-fallow in the Great Plains, also suspected as the source of negative serial correlation in the disturbance term.

Wheat Yield Equation

A new methodology using a nonstochastic difference equation was applied to estimate aggregate U.S. wheat yield response. Independent variables are trend, t, season average wheat price, P_t, and planted acreage, A_t, and the dependent variable is bushels per acre, Y_t. The equation used in this study was estimated for the sample period of crop years 1953/54 to 1975/76:

$$
\begin{aligned}
(3)\quad Y_t = & -31.87 + \underset{(6.8)}{.350t} + \underset{(4.8)}{5.66P_{t-1}} \\
& + \underset{(6.7)}{4.67P_{t-3}} + \underset{(2.1)}{1.82P_{t-5}} - \underset{(6.7)}{.000182A_t} \\
& + \underset{(8.9)}{.791E(Y_{t-1})} + u_t, \text{ and}
\end{aligned}
$$

$$
(4)\quad u_t = -\underset{(5.4)}{1.06u_{t-1}} - \underset{(2.2)}{.44u_{t-2}} + \epsilon_t.
$$

$$\bar{R}^2 = .900 \text{ and } s = 1.10$$

The expression $E(Y_{t-1})$ is the unconditional expectation of Y_{t-1}, which implies a first-order, nonstochastic, difference equation in the mean of the dependent variable (Burt). The unconditional expectation implies that $E(Y_{t-1})$ does not take account of the information available from the serially correlated disturbance term as given in (4). Prices are deflated the same as in the acreage equation.

The estimation procedure can be interpreted as maximum likelihood estimation of a rational lag specification with the denominator of the rational function being the same for all independent variables (Burt). The parameter estimators of P_{t-2} and P_{t-4} were highly correlated (negatively) with adjacent lagged prices, which destroyed any individual significance on the prices; therefore, these two prices were omitted. The implied lag distribution is smooth in spite of the omitted price variables. The negative serial correlation most likely stems from crop rotation constraints, particularly with summer-fallow in the Great Plains.

Domestic Wheat Demand Equations

Because United States export decisions appear to be made independently of those for domestic consumption and are dominated by exogenous world events, we assumed that price is largely exogenous for purposes of estimating domestic demand.

Per capita demand for food (bushels) was estimated for the period of crop years 1950/51 to 1974/75:

$$
\begin{aligned}
(5)\quad C_t = & 1.264 + \underset{(2.0)}{6.735/(t + 10)} \\
& - \underset{(2.4)}{.0284P_t} + \underset{(1.8)}{.440E(C_{t-1})}.
\end{aligned}
$$

$$\bar{R}^2 = .990 \text{ and } s = .022$$

The reciprocal trend was introduced to reflect the increasing margin over time between the consumer and farm level prices, and the number 10 in the denominator was obtained by a search on the error sum of squares. The first-order difference equation reflects habit formation in consumer behavior and implies a geometric lag distribution on price. Various models which were tried suggested that the net effects of the trend and $E(C_{t-1})$ terms were seriously confounded. Correlation between these two parameter estimators is $-.9986$ in (5), which explains the low t-ratios on these two parameter estimates. The price variable was adjusted for the 75¢ per bushel marketing certificates during 1964–73 and deflated by the food price index. Per capita income was insignificant when introduced into (5).

Total domestic demand for livestock feed was estimated for the crop years 1956/57 to 1975/76, giving

$$
\begin{aligned}
(6)\quad QF_t = & -460{,}200 - \underset{(2.2)}{112{,}400P_t} \\
& + \underset{(1.2)}{74{,}240FGP_t} + \underset{(1.8)}{8.857GCAU_t},
\end{aligned}
$$

$$\bar{R}^2 = .636 \text{ and } s = 43.410$$

where QF is thousand bushels of wheat fed to livestock; P and FGP, as well as the deflator, are the same as in the acreage equation; while $GCAU$ is grain consuming animal units (thousands).

Wheat seed demand was estimated as a linear function of seeded acres,

$$
(7)\quad QS_t = -2702 + \underset{(44.6)}{1.195A_t},
$$

$$\bar{R}^2 = .991 \text{ and } s = 810$$

where QS is thousand bushels of wheat demanded for seed, and A is thousand acres seeded. The sample period was 1956/57 to 1975/76.

Autoregressive Export Price Equation

Rather than try to estimate an econometric model to explain demand for U.S. wheat exports, a Box-Jenkins type time-series analysis was made on market price at the Gulf of Mexico ports. Variables such a world stocks of grain are reflected indirectly in the systematic structure of the time-series model, i.e., lagged prices and moving average error terms. An advantage of this approach for the wheat storage model is parsimony in the number of state variables needed, and also, simplifications in the stochastic transition equations to describe movement of the state variables over time.

The time-series model of price changes can be interpreted as representative for average U.S. exports over the time-series sample used in the estimation. Then, an independent estimate of demand elasticity for U.S. wheat exports, where quantity is measured from the time-series mean, is introduced into the time-series equation for export price.

The final equation from the time-series analysis over the sample period 1959–75 was

$$(8)\quad ln(WP_t) = .1604 + \underset{(6.3)}{.7127}ln(WP_{t-1}).$$
$$\bar{R}^2 = .827 \text{ and } s = .117$$

The Gulf price, which we denote by *WP* to symbolize "world price," is deflated by the U.S. consumer price index. A second-order autoregressive equation was only marginally significant over the first-order equation in (8), and would imply another state variable in the storage model. A moving average error jointly with the first order autoregressive specification was tried, but with little improvement. A dummy variable was introduced for 1973, because that year consistently gave an unusually large residual, suggesting an outlier.

The price elasticity of demand for U.S. wheat exports was estimated by aggregating world regional demand elasticities estimated by Konandreas; average quantities exported to individual regions were used as weights. This elasticity of −2.5 was close to the −3.0 estimated directly by Konandreas and Schmitz.

Let η be the estimated price elasticity, while $\bar{p}$ and $\bar{x}$ denote mean price and exports, respectively. Then a term to reflect the influence of U.S. exports on price is given by

$$(9)\qquad dp/dx \simeq \bar{p}/\bar{x}\eta.$$

Price at the Gulf, our proxy for world price, was specified to obey the following relationship derived from (8) and (9),[2]

$$(10)\quad WP_t = 1.222(WP_{t-1})^{.7127} + .95(10)^{-6}(x_t - \bar{x}),$$

with exports measured in 1,000 bushels. Mean price and exports were \$1.81 and 765 million bushels, respectively.

Equation (10) is viewed as the demand for U.S. wheat exports. Note, however, that the price variable is price at the Gulf, while prices in the other equations are average prices received by farmers. A single price variable was obtained by using the Gulf price as a "standard" and regressing average price received by farmers (excluding subsidies) on the Gulf price.

The Stochastic Storage Model

Computational solutions are obtained by approximating the continuous state variables by many discrete intervals which results in a Markovian sequential decision process with a finite number of states. The only decision variable is quantity of wheat exported that indirectly controls year-to-year carryover. Otherwise, free market conditions are assumed in the wheat industry with no government controls on production.

Because the disturbance term in the export price equation (10) is assumed unknown at the time a storage policy decision is made, a specific level of exports does not determine price but only the probability distribution. The probability distributions for price and the disturbances in supply and demand in conjunction with the state variables then determine the distribution of domestic consumption, production, and ending carryover for the ensuing crop year. If exports had been estimated as a function of world price with the random disturbance reflecting variations in exports for a given price, then price (or at least a "target" price) would have been a logical choice of decision variable (Taylor and Talpaz). Some studies, e.g., Cochrane and Danin, have assumed that random disturbances are known at the time decisions are made; this makes the

[2] One problem with this approach in a dynamic optimization model is that exports can be controlled over time to manipulate this lagged price which we would like to assume is exogenous. The sensitivity analysis on misspecifications in the model which are reported later suggest that this could be somewhat of a problem.

choice of a decision variable much more flexible, in fact, arbitrary.

Stage length, or interval between decisions, is one year. It should begin when most information is available for decision making—we chose 1 September. Stocks then become last year's carryover plus production from the harvest just completed. The primary price used as a state variable is average price at the Gulf during the preceding crop year which ended 30 June.

In a straightforward application of dynamic programming to the wheat storage model, there is a total of fifteen state variables. For example, the acreage equation in (1) requires that September price, first- and second-order lagged seasonal prices, and first- through third-order lagged acreages be entered as state variables, making a total of six. Another state variable would be needed to incorporate information stemming from serial correlation in the disturbance term. In general, a lagged price or quantity variable in a component equation of demand or supply requires representation via an extra state variable in the dynamic optimization model. Also, a serially correlated disturbance term in a component equation of demand and supply implies state variables equal in number to the order of serial correlation. The implicit variables $E(Y_{t-1})$ and $E(C_{t-1})$ in (3) and (5), respectively, are treated as lagged variables in this respect and each requires a state variable in the decision model.

A Proximate Solution Method

As it is not feasible to work with a model containing fifteen state variables, some approximation had to be developed. The method used is a variant of that suggested by Arrow.

The general recursive equation of dynamic programming is

$$(11) \quad v_n(\mathbf{y}) = \underset{x}{\text{Max}} \Big(g_n(\mathbf{x},\mathbf{y}) + \alpha E\{v_{n-1}[T_n(\mathbf{x},\mathbf{y})]\}\Big),$$

where $\mathbf{y}$ and $\mathbf{x}$ are vectors of state and decision variables, respectively, and $E[\cdot]$ is the expectation operator. In the wheat storage problem $v_n(\mathbf{y})$ is the present value of expected net benefits over an n-year planning period when following an optimal storage policy and given that the initial state vector is $\mathbf{y}$; α is the discount factor with $0 < \alpha < 1$. The function $g_n(\mathbf{x},\mathbf{y})$ is expected annual net benefits from the first year of n future years, while $T_n(\mathbf{x},\mathbf{y})$ is the transformed vector of state variables at the beginning of a planning horizon of $n - 1$ years. Actually $T_n(\mathbf{x},\mathbf{y})$ is a random variable and the function notation is used to show that $\mathbf{x}$ and $\mathbf{y}$ enter as parameters in the multivariate distribution function of the vector of state variables. The subscript n on $T_n(\mathbf{x},\mathbf{y})$ implies that the probability distribution is permitted to change from stage to stage in the decision process.

The approximation discussed by Arrow is to replace $v_{n-1}(\cdot)$ in (11) by an estimate of some kind. The usual computational method of dynamic programming calculates the function $v_n(\cdot)$ recursively starting with $v_0(\cdot)$ as a given function. But now we are considering some a priori estimate of $v_{n-1}(\cdot)$ in order to estimate the optimal decision rule for stage n only. It is seen from (11) that if $v_{n-1}(\cdot)$ were a known function, the optimal decision for stage n could be obtained from a static optimization algorithm.

The approximation suppresses all state variables except two judged to carry the most information in the decision process when considering all components of the demand and supply equations jointly with the world wheat price equation. Obviously, stocks of wheat are a crucial state variable, and the second variable chosen was wheat price lagged one year (Gulf price being used as a standard instead of average price received by farmers). Details of how the model in (11) can be modified to suppress certain state variables are discussed later.

The following dynamic programming recurrence relation, containing two state variables and one decision variable, is introduced to explain the method

$$(12) \quad f_n(s,p) = \underset{x}{\text{Max}} \Big[G_n(x,s,p) + \alpha E\Big(f_{n-1}\{s - x + w_n(x,p), [1.22p^{.713} + .95(10)^{-6}(x - \bar{x})]u\}\Big)\Big],$$

where x, s, and p are wheat exports, stocks, and season average price last crop year, respectively; $G_n(x,s,p)$ is expected annual net benefits in stage n, and $w_n(x,p)$ is a random variable representing net production after subtracting domestic consumption. The transformation equation for the price state variable is (10) with a multiplicative random error, u, which does not depend on the decision or state variables.

Step one. The first step truncates trends in the component equations of demand and supply so that the decision process is stationary over

time. Therefore, the subscript n is redundant on $G_n(x,s,p)$ and $w_n(x,p)$ for this first step of the procedure. An arbitrary value such as zero is assigned to $f_0(s,p)$ and the usual recursive computational method (see Bellman) is used to solve (12) for a reasonably long planning horizon which we denote by k. The application used k equal to 20, corresponding to years 1981–2000.

The most important output from this first-step solution is the expected value function, $f_k(s,p)$; with it we are ready to begin the second step of the approximation procedure and start bringing in additional information associated with the other state variables.

The relationship between chronological time, stages of the decision process, and dates used in the application is given in figure 1. The time at which an actual decision is to be made is t equal to zero, which corresponds to stage number $k + 5$ and year 1976. The highest order lagged variable in the component equations of supply and demand is the fifth-order lagged price in the yield equation in (3); this highest lag determined the configuration chosen in figure 1. At stage $k + 1$, which corresponds to t equal to 4, the fifth-order lagged price is a known datum, but would be unknown for t greater than 4. Therefore, only the two state variables of the model are known information when $t \geq 5$, i.e., $n \leq k$.

Remaining steps. In the second step, we set n equal to $k + 1$ in (12), which lets us substitute the known function $f_k(s,p)$ for $f_{n-1}(s,p)$ in (12). The expected immediate net benefit function, $G_{k+1}(x, s, p)$, is calculated with price lagged five years (measured from the beginning of the year associated with stage $k + 1$) taken as a given datum. Likewise, the fifth-order lagged price is taken at its actual level in the definition of the random variable $w_{k+1}(x,p)$. Recognition of this known fifth-order lagged price at stage $k + 1$ gives an improvement in the calculation of $f_{k+1}(s,p)$ which would not be possible by merely iterating the general two-state-variable model of the first step in the approximation one more time.

At stage $k + 2$, not only the fifth-order but also the fourth-order lagged price is known information. However, the latter does not enter any of the components of demand or supply. Therefore, the third step of the approximation is simply a repeat of the second step; but, of course, the fifth-order lagged price is measured from the year associated with stage $k + 2$ and is a different value (usually) than used in the second step. This provides us with $f_{k+2}(s,p)$.

At stage $k + 3$, third- through fifth-order lagged prices are known data as well as third-order lagged acreage, which appears in the acreage response equation in (1). The fourth step in the approximation takes these lagged variables as known data with respect to the probability distribution of $w_{k+3}(x,p)$ and the expectation operation to obtain $G_n(x,s,p)$, and another iteration of (12) is made to obtain $f_{k+3}(s,p)$.

The fifth step of the approximation puts us at stage $k + 4$, where lagged prices and acreages of orders higher than the first are known data. Probability distributions associated with (12) are defined with these lagged variables as given data, and another iteration yields $f_{k+4}(s,p)$. Second-order serial correlation in the disturbance of the yield equation in (3) could have been incorporated into the probability distributions too, but we did not do so in the application.

The last step of the approximation brings us to stage $k + 5$, the beginning of the actual planning horizon for which a decision is wanted, and all lagged variables including first order are known data. Also, the information contained in the serial correlation of the disturbances in (1) and (3) can be used by the standard forecast methods. We take all of this information into account in the definition of probability distributions to make the final iteration on (12), thus obtaining $f_{k+5}(s,p)$ and the final decision rule from the maximization operation in (12).

A review of the method reveals successive improvement in the approximation of $v_{n-1}(\cdot)$ in (11). Each iteration, beginning with stage k + 1, brings in known data at that stage for all of the state variables, not just s and p. At the final stage $k + 5$, all the state variables are known data and have an opportunity to exert their

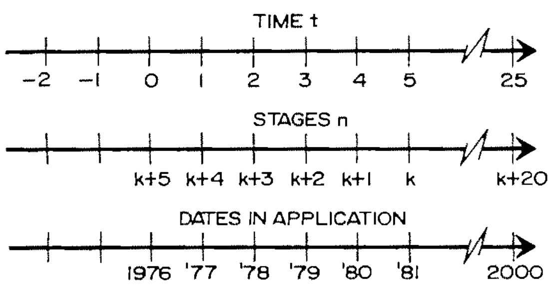

Figure 1. Relationship between stages and chronological time

influence on the final decision. Therefore, at the final stage of calculations where the decision rule is going to be actually applied, we have a relatively good approximation for $v_{n-1}(\cdot)$, and the final optimization is viewed as an application of Arrow's proximate method to the original problem containing the full set of state variables.

Let it be clear that this entire computational process should be repeated each year, including an annual update of econometric relationships, so that decisions are based on the most recent information available.

State variable suppression. Now return to the problem of suppressing state variables, a necessary task for carrying out the proximate solution method. In principle, state variables in a stochastic model can be suppressed by using an unconditional joint distribution instead of a conditional distribution for the transition of the remaining state variables from stage to stage. However, a difficulty arises because the probability distribution is dependent on the decision rule applied. An iterative procedure could be used where an a priori decision rule is used to get the unconditional joint distribution of the state variables not suppressed; then the optimal decision rule is derived taking this distribution as given. The next iteration would use that decision rule just calculated in place of the a priori rule, and the computations completed again. Several iterations would be expected to give a convergent decision rule which would then be taken as the optimal decision rule for the model with a reduced number of state variables.

Although the methodology described in the above paragraph was the guiding principle, a more expeditious method was used in the wheat storage problem. The existence of a market equilibrium price for the wheat industry in the United States, when the trends in yield and domestic food demand are truncated, suggested a simple procedure to suppress all of the state variables except wheat stocks and last year's price.

We illustrate the procedure with the acreage equation in (1). First, an estimate was made of long-run equilibrium price of wheat which permitted long-run acreage to be calculated from (1). This long-run acreage was then substituted into (1) in place of the three lagged acreage variables which collapses these variables into the intercept of (1). Second, each price variable in (1) was regressed on the Gulf price of crop-year $t-1$, and these three simple regressions were used to replace the prices in (1) with a single price, *viz.*, the price state variable. The final result is a linear equation in the price state variable, and all lagged variables have been removed except the state variable.

The final task is in handling the stochastic specifications of the acreage equation. As a compromise in the direction of a Bayesian approach, the standard deviation of the disturbance term was approximated by the standard error of prediction instead of the standard error of the estimate, thus taking into account the variability of the parameter estimators in the equation. However, the standard error of prediction changes with the values assigned to the independent variables, so we took the value for 1976 as an approximation throughout, in order to simplify the computations. The serially correlated disturbance was handled by using its unconditional distribution which ignores the dependence structure of (2) and inflates the variance of the disturbance term; that is to say, we used u_t instead of ϵ_t in (2) as the disturbance.

The three simple regressions between lagged average prices received by farmers and the Gulf price introduce additional disturbance terms into the simplified acreage equation. We included the disturbance terms in these regressions when making the substitutions for prices and followed through the statistical implications for increased variability in the overall disturbance term of the acreage equation. In so doing, parameter estimates were taken as given at their point estimates in the price regressions, and the standard deviations of the disturbances were estimated by the standard errors of the estimate for the respective equations.

Space does not permit giving comparable details on how the other component equations of demand and supply were simplified, but the estimated equilibrium price was exploited to reduce each equation to only one independent variable, *viz.*, the price state variable. The final result provided a model with all state variables suppressed except for wheat stocks and first-order lagged price at the Gulf. This storage model can be interpreted as an approximation which should provide good results if existing conditions, and the recent history of those conditions, are not "too far" from the equilibrium state. We rely on the successive iterations for stages $k+1, k+2, \ldots, k+5$ to

accommodate initial conditions substantially removed from the long-run equilibrium.

For the last few iterations where known information on all state variables is exploited, equations such as that for acreage were simplified in all stages except $k + 5$, but known values of lagged variables and trend were utilized in the simplifications. In general, the variances of disturbance terms in the simplified equations become smaller as the stage increases from k to $k + 5$, i.e., as we move in time from $t = 5$ to $t = 0$. At stage $k + 5$ ($t = 0$) when all lagged variables are known data, the variance of the disturbance term was taken as the square of the standard error of prediction in (1).

The required estimate of long-run equilibrium price can be obtained by solving the system of equations for the wheat industry which encompasses all components of demand and supply. The dynamic equations must be transformed into their long-run forms and trends truncated at some arbitrary level. Prices received by farmers are transformed into price at the Gulf by a linear regression between these two prices. Equilibrium price was calculated to equal \$3.22 in 1976 dollars (\$1.89 in 1967 dollars) which is reasonably close to expected value of price from the optimization model, \$3.14.

Of course, the component demand and supply equations derived by suppressing state variables are not long-run equations in the sense of the above paragraph, even the ones associated with stages 1, 2, . . . , k. These equations with suppressed state variables are annual adjustment equations, but with only the price state variable as an argument, and the intercepts have been adjusted to correspond to a recent history of long-run equilibrium prices and quantities.

Probability Distributions for Net Production

The aggregate supply function for wheat is obtained by multiplying (1) and (3) together, which gives a rather complicated structure in the random disturbance. Because the yield equation contains acreage as an independent variable, the multiplication results in a term involving the product of the disturbance terms from the separate yield and acreage equations. This complicating factor in the stochastic specification of supply led to the use of a Monte Carlo approach to estimate a cumulative distribution function (CDF) for net production, i.e., production minus all domestic consumption components. Net production is the random variables $w_n(x,p)$ in (12).

Technically, a separate CDF would need to be estimated for each discrete pair of values (x,p) used in the computational algorithm at a given stage n. The long-run model for stages 1, 2, . . . , k assumes a stationary decision process, thus requiring only one set of CDF's, but a separate set of CDF's is required for each stage $k + 1$, $k + 2$, . . . , $k + 5$.

In the empirical study, we made a further simplification by removing exports, x, as a parameter in the CDFs; only the price state variable, p, entered as a parameter. The relatively small impact that changes in exports would have on domestic consumption was considered quite trivial relative to the variability in the random error for net production.

For each stage where a separate set of CDFs was required, a separate CDF was estimated for each discrete price interval. Usually a sample of 500 was used in the Monte Carlo procedure to get sample points for the CDF, and then a polynomial was fitted to these sample points. Normally distributed disturbances were assumed in the various component equations of demand and supply.

The other random variable, u, in (12), which is associated with the price state variable, was assumed to follow the log-normal distribution and to be independent of the net production random variable, $w_n(x,p)$.

The Criterion Function

Two separate criterion functions are used in the analysis: (*a*) domestic, and (*b*) world welfare. The domestic criterion is the sum of domestic consumers' and producers' surpluses minus storage costs. The world welfare criterion contains consumers' surplus associated with the export demand equation in addition.

Computation of the annual expected net benefit function under either criterion was greatly simplified by replacing random variables by their mean values in the demand and supply equations. In the case of the component demand equations, this simplification is justified by the Simon-Theil certainty equivalence theorem for quadratic criteria functions because the demand equations are linear, making the associated value measures quadratic. However, the supply equation is quadratic in

price after multiplying yield and acreage together, which makes the certainty equivalence theorem only approximately valid (Malinvaud). Let it be clear that we are appealing to the certainty equivalence theorem in a limited sense for the overall optimization problem, *viz.*, for the single-stage maximizations in (12) and only with respect to how $G_n(x,s,p)$ is calculated. The stochastic linkage from stage to stage through the state variable transformation equations, containing the random variables $w_n(s,p)$ and u, does not rely on linear approximations through the certainty equivalence theorem.

The usual theoretical justification for using areas under demand and supply equations as measures of social value and cost is based on static demand and supply equations (Hotelling). The food demand, acreage, and yield equations for wheat are dynamic because they contain lagged values of the quantity measures and prices in their right-hand sides. These equations can be transformed into long-run equations by well-known manipulations, as contrasted to their interpretation as conditional short-run equations when presented as dynamic regression equations. It would appear that a long-run interpretation of these equations would more nearly fit received theory for static equations in regard to measuring social values and costs.

The yield equation presented special problems because yields are clearly a nonstationary process and have been subject to rapidly changing technology during the sample period used to estimate (3). It was our judgment that the term for $E(Y_{t-1})$ is confounded with trend and should not be used to derive a long-run yield response equation with respect to price. Therefore, only the sum of the lagged price coefficients was used to derive the long-run relationship between yield and price; the trend and $E(Y_{t-1})$ terms were truncated and combined with the intercept.

The long-run acreage and yield equations were multiplied together to get a long-run supply equation defined with price as the independent variable. Expected quantity of wheat produced for given values of the state variables is calculated from the relevant acreage and yield equations with suppressed state variables, and then the long-run equation is used to calculate area under the supply curve associated with that quantity.[3] This value plus storage costs is taken as expected social cost in the calculation of $G_n(x,s,p)$. Separate yield equations, and consequently, separate long-run supply equations are used for stages $k+5$, . . . , $k+1$, and another equation for stages 1, 2, . . . , k.

The demand equation for domestic food in (5) is transformed into a long-run equation and trend is truncated at the 1976 level; the marginal effect of trend is trivial after 1976 ($t = 26$ in 1976). For an expected value of domestic food consumption, this equation provides the basis for calculating gross value of social benefits per capita, and multiplication by a suitable population figure gives aggregate value for food consumption.

The price variable in both the domestic food and livestock feed demand equations for wheat is the current average price received by farmers. We need a relationship between that price and lagged price at the Gulf, which is our state variable, and we also want this relationship to reflect the impact of exports on price. A simple linear regression was run between average market price received by farmers and lagged price at the Gulf. Then a term for exports was introduced by using an a priori estimate of the elasticity of demand for U.S. exports; the method is the same as used to get from (8) to (10). This price relationship was substituted for the price variable in each demand equation to provide an estimate of mean quantity consumed in a given usage. The resulting equation reflects both the price state variable and level of exports, which is the decision variable.

The livestock feed demand equation in (6) is already static. The two extra independent variables, besides price, are combined with the intercept by setting these variables at some representative levels; we used mean values in the time-series sample.

The demand equation for seed does not contain price, only acreage planted. Therefore, we assumed that the small amount of wheat used for seed has a gross marginal social value approximately equal to average price received by farmers during the year in which the seed is used.

Either market value or social value is calculated easily for the export demand equation because exports are the decision variable and we have the autoregressive relationship for export price given in (10). For a given level of

[3] These equations are not for the long-run, but instead, are annual adjustment equations, the derivation of which was explained in the discussion of how to suppress some of the state variables; acreage was used as the illustration.

the price state variable, (10) gives a linear demand equation for exports. We now have covered all the various components needed to estimate the expected net benefit functions, $G_n(x,s,p)$, in (12).

Optimal Fixed Storage Capacity

Thus far storage capacity restrictions have been avoided, but the optimization in (12) is tacitly subject to storage capacity constraints. Recall that wheat stocks, s, taken as the sum of current harvest and carryover from previous years, is a state variable which is known information, and exports, x, is the decision variable. Let C denote fixed storage capacity for wheat; then we impose the constraint,

$$x \geq s - C. \tag{13}$$

The constraint in (13) implies that capacity, C, is used to store wheat for domestic consumption and carryover of wheat to the following year, but none of this capacity is used for exports.

First, it must be recognized that the storage model assumes all activity within a year takes place instantaneously at a single point within the year, which makes (13) an appropriate constraint. The harvest is not completed instantaneously, nor does domestic consumption all take place at the end of the year anymore than do exports all leave the country the day after harvest. The most complicating factor of all is that common storage facilities are used for all grains, which makes a specific capacity for wheat somewhat artificial. Nevertheless, specification of (13) as a constraint in the storage model provides useful information on the economics of wheat storage.

Solution of the optimal storage problem for a given storage capacity provides a present value measure of net benefits for an initial state of the decision process. A search procedure can be used to find optimal capacity, or a few points on the functional relationship can be calculated to estimate the entire function.

Empirical Results

Most of our numerical computations were done under the specification of unlimited storage capacity because total grain storage capacity was thought to be so large that the optimal decision rule would not be affected by the existing upper limit. (The results reported below support this position.) These results are discussed before considering optimal storage capacity and distribution of benefits from storage. All dollar values reported are in 1976 dollars.

Unlimited Storage Capacity

Variable costs of storage were taken as 6¢ per bushel annually (Schienbein) and a discount rate (net of inflation) of 6% was used to calculate present values. Stocks of wheat (production plus old-crop-carryover) were allowed to assume fifteen levels, starting at 1,000 and ending at 3,800 million bushels in increments of 200 million. Last season's price at the Gulf could assume ten values, \$1.00 to \$5.50, at 50¢ intervals. Exports were permitted eleven values, 50 to 2,050 million bushels, in increments of 200 million.

Computations were performed to determine optimal exports for the fall of 1976 when the existing state was 2,800 million bushels of wheat and a price of \$4.00. Optimal exports were 1,250 and 1,850 million bushels for the domestic and world criteria, respectively. Actual exports indicated by the world criterion are extremely high by any standard, but production projected from the model for the following year also is high, which substantially reduces the value of carryover into 1977. Also, the relatively high price of \$4.00 makes marginal net benefits favorable. Marginal benefits fall at one-half the rate under the world compared to the domestic criterion.

An advantage of the Markov process dynamic programming model is the direct availability of probability distributions for the state and decision variables over time. Marginal distributions of wheat stocks and prices over time under the optimal decision rule associated with the domestic criterion are given in tables 1 and 2; expected values are given at the bottoms of the respective tables. There is a pronounced downward trend in expected price (table 2) from the initial value of \$4.00 in 1976 to \$2.16 in 1979, with some sign of recovery in 1980 and a limiting average price of \$3.14. These results suggest that even under an optimal storage policy based on the domestic criterion, depressed prices are likely through 1980 without any supply control measures by the government. As can be seen by the last row of table 1, expected wheat stocks are over 3.0 billion bushels through 1980, implying an old-crop carryover in excess of 1.0 billion bushels each year during the same period.

Under the world welfare criterion, expected

Table 1. Marginal Probabilities of Wheat Stocks under the Domestic Criterion

3,400	.	.1290	.2677	.3059	.1620	.0038
3,600	0	0	.0693	.1001	.0314	.0010
3,800	0	0	.0003	.0065	.0010	.0002
Expected stock	2,800	3,140	3,200	3,250	3,100	2,140

price declines more abruptly from $4.00 in 1976, to $2.07 and $2.02 in 1977 and 1978, then increases to $2.29 and $2.44 in 1979 and 1980, respectively. The limiting price far in the future is $3.14, the same as under the domestic criterion. Expected wheat stocks under the world criterion are 2,540, 2,660, 2,860, 2,810, and 2,010 million bushels in 1977, 1978, 1979, 1980, and in the limit, respectively. These lower stocks are consistent with the implied larger export levels and lower prices under the world as compared to domestic criterion. The lower long-run expected stocks show less advantage to storage under the world criterion, an intuitively plausible result because the marginal revenue curve does not decrease as fast under the world criterion.

Table 2. Marginal Probabilities of Wheat Price at the Gulf under the Domestic Criterion

Price (1976$)	Year					
	1976	1977	1978	1979	1980, . . . ,	Limit

Expected price	4.00	3.05	2.37	2.16	2.24, . . . ,	3.14

Differences in expected old-crop carryover between the domestic and world criteria are 600, 540, 390, 290, and 130 million bushels in 1977, 1978, 1979, 1980, and the limit, respectively. The limiting expected carryovers of old-crop are 610 and 480 million bushels under the domestic and world criteria, respectively. Limiting levels of expected production, consumption, and exports under either criterion are 1,528, 727, and 801 million bushels, respectively. Production is the product of an expected yield and acreage of 31 bushels and 49.2 million acres.

The asymptotic model, which used demand and supply equations with lagged variables suppressed and replaced by the price state variable, can be viewed as a limited information decision model. It is quite useful for showing the general structure of the decision rule and other aspects of the dynamic decision problem because the associated stochastic process is stationary. The optimal decision rules are invariant over time and can be given by 2-by-2 tables for the discrete variable approximations used in the computations. This asymptotic decision rule is given in table 3 for the domestic criterion with + or − used to show the changes necessary to transform the export level to that associated with the world criterion. A + or − indicates to add or subtract 200 million bushels, and a double + requires adding 400 million bushels to get the world criterion decision rule. Perusal of table 3 shows that the decision rule for the world criterion exports higher levels at relatively high stocks and prices, and vice versa, compared to the domestic criterion.

The decision model which utilized all information available in 1976 by means of the proximate procedure described earlier will be referred to as the 1976 model to distinguish it from the asymptotic model, the decision rule for which is given in table 3. Value of the extra information provided by the proximate procedure for the 1976 model can be quantified by substitution of the asymptotic decision rule of table 3 for the separate decision rules obtained from the 1976 model in years 1976–79. The difference in expected present value of net benefits under the "optimal" and asymptotic decision rules, under a given criterion, provides a quantitative measure of the extra information. These present values were $609 million and $172 million under the domestic and world criteria, respectively, for a twenty-four-year planning period; annual amortized

3,200	650–	850–	850+	1,050+	1,250+	1,250++	1,450++	1,450++	1,650++
3,400	650	850	1,050	1,050+	1,250+	1,450+	1,450++	1,650++	1,850+
3,600	850–	850	1,050	1,250	1,450	1,450+	1,650+	1,650++	1,850+

Note: Export levels in the table are for the domestic criterion; exports under the world criterion are the same with the following exceptions: + add 200, ++ add 400, – subtract 200.

values are $48.5 million and $13.7 million. The above values are dependent on the initial state and recent history of wheat prices. If wheat prices have been near the equilibrium for an extended period, the decision rule from the asymptotic model should be nearly optimal for the existing situation, making the extra information of little value.

We know that under sufficiently high exports marginal revenues are negative, and marginal net revenues, which account for supply costs, become negative at lower exports. Therefore, we might expect that the marginal value of wheat stocks would become negative at sufficiently high stocks under the domestic criterion because the model does not allow disposal of wheat outside of the market. Marginal values of the state variables are given by the partial derivatives of the function $f(s,p)$ in (12). Discrete approximations are readily obtained from the numerical results of the dynamic programming solutions. Under the domestic criterion, the marginal value of stocks in 1976 was -30¢ per bushel, while under the world criterion the same measure was 70¢. Marginal values remain positive for all states considered under the world criterion.

The marginal value of wheat stocks becomes negative at about 2,300 million bushels under the domestic criterion for conditions in 1976, which is only about 200 million bushels more than U.S. production that year. Therefore, taking production as given, we can say that the marginal value of old-crop carryover in 1976 becomes negative at about 200 million bushels. This somewhat surprising result stems from the recent history of high prices and the associated increase in production capacity of the wheat industry, as reflected by the dynamic acreage and yield equations in (1) and (3). The asymptotic model, which assumes a recent history of prices near the equilibrium, does not show negative marginal values for stocks until they reach 3,400 million bushels, under the domestic criterion, and the same value of $4.00 for the price state variable as existed in 1976.

Storage Capacity Analysis

We approach the issue of optimal storage capacity in a rather simplified way. Suppose no storage existed and initial stocks of wheat and price were given, then we ask the question: What would be the optimal capacity to build now if capacity would never be changed again? This approach to the problem avoids treating storage capacity changes in a sequential decision framework jointly with export and storage control.

Initial stocks and price have a large influence on optimal capacity determined by this method. We could think of applying our method sequentially under the simplifying assumption that the storage facilities have infinite life, thus removing the problem of attrition in the old construction. In this framework, an upper bound on optimal fixed capacity can be estimated by taking the initial state as the largest stocks and lowest price which is

ever likely to occur. Based on the asymptotic probabilities in tables 1 and 3, together with historically experienced conditions, we chose the initial state of 3,200 million bushels and \$2.50 for stocks and price.

The asymptotic model was used to evaluate storage capacity and distributional impacts because the computations were much simpler and saved considerable computer time. We would expect that a somewhat higher storage capacity would be justified under the 1976 model.

Separate dynamic programming solutions were obtained for fixed capacities of 1,000 million to 3,000 million bushels by increments of 200 million. The present value of fixed costs of storage, for the same length of planning horizon, were calculated for each capacity level. Amortized fixed costs were taken at 16¢ per bushel annually (Schienbein). Then net present values were calculated for the various levels of capacity while taking the initial state as given. Quadratic interpolation was used to determine optimal capacity under each criterion. The results were 2,100 and 2,000 million bushels under the domestic and world criteria, respectively.

Optimal capacities are quite sensitive to the initial price specified. Actual conditions existing in 1977 were 3,200 million bushels and \$3.00, which is the same as above except price is \$3.00 instead of \$2.50. Optimal capacities under the domestic and world criteria for the 1977 conditions are 2,000 million and 1,800 million bushels, respectively. If initial conditions are set equal to the long-run equilibrium values of 2,000 million bushels and \$3.00, optimal storage capacities are 1,400 million and 1,100 million bushels.

Clearly, an economically justifiable storage capacity for wheat is substantially less than that now existing in the United States, which is near 3,000 million bushels if total grain storage is prorated according to production. In fact, expected present value of net benefits with only variable costs of storage deducted is essentially constant between 2,600 million and 3,000 million bushels capacity under either criterion.

In order to give some perspective to total gains from storage, the gain in going from 1,000 million to 2,000 million bushels capacity (the latter is near optimum) under the domestic criterion is 300 million dollars annually, given the initial state of 3,200 million bushels and price of \$3.00. The comparable figure for the world criterion is \$190 million. The base of 1,000 million bushels is about as low as would make any sense; with equilibrium consumption at 730 million, this leaves maximum capacity for old-crop carryover equal to 270 million bushels. In the context of current politics, these annual values of \$300 million and \$190 million in benefits might be compared to the subsidy to wheat farmers in direct payments which is estimated at \$600 million for the 1978 crop.

Benefit Distribution and Sensitivity Analysis

An important consideration in commodity storage programs is the distribution of benefits. In the context of U.S. wheat storage net benefits can be partitioned into components associated with domestic consumers foreign consumers, domestic producers, and storage costs. Recent theoretical literature on storage (Just et al., Turnovsky 1974, 1976) suggests that the distribution of benefits is likely to be affected by curvatures of demand and supply equations and by the nature of disturbance terms, additive versus multiplicative. Several alternative specifications were evaluated by applying the optimal decision rule from our standard model to the alternative specification.

As a point of reference, the standard model can be described as having linear domestic demand, quadratic supply (concave downward with price on the vertical axis), and linear foreign demand with lagged price taken as fixed [autoregressive price structure as given in (10)]. Domestic demand disturbances are additive while the disturbance in foreign demand is multiplicative. Supply has a combination additive/multiplicative disturbance arising from additive disturbances for separate yield and acreage equations.

The alternative specifications are: (*a*) linear supply with the same form of disturbance as in the standard model, yield was taken as fixed instead of dependent on price; (*b*) nonlinear domestic demand equations for food and livestock feed with disturbances unchanged from the standard model, the nonlinear forms were the familiar Cobb-Douglas function; (*c*) nonlinear foreign demand with the additive term in (10) replaced by a multiplicative factor of the form $\exp[-b(x - \bar{x})]$, the disturbance term was left the same as in the standard model; and (*d*) static linear foreign demand with addi-

tive instead of multiplicative disturbance, the autoregressive structure of (10) was deleted. The same elasticity of demand for U.S. exports, equal to −2.5, was used in the changed specifications of (*c*) and (*d*), above, together with the condition that mean price and exports satisfy the equation, which gave unique estimates of the two-parameter equations. Nonlinear demand equations were fitted the same way using the elasticities from the linear equations of the standard model at mean prices and quantities.

Results on the distribution of benefits under the various specifications are given in table 4 for the domestic and world criteria. These figures are measures of the change in benefits when storage capacity is increased from 1.0 billion to 2.0 billion bushels with an initial state of 3.2 billion bushels of stocks and a price of $3.00, which is the state which existed in 1977. Values in the last column are for the criterion itself; the domestic criterion leaves out foreign consumers surplus. Remember that the same decision rule was applied throughout table 4, and it is optimal for the standard model only. The units are such that the values in the table can be transformed into cents-per-bushel increase in storage capacity by merely moving the decimal one place to the left. These benefit figures are net of both fixed and variable costs of storage.

It is encouraging that the distribution of benefits is qualitatively the same across all specifications, i.e., the signs on the benefits remain unchanged, because some of the theoretical results suggest that this might not have been the case. Domestic producers clearly gain from a storage program, while domestic and foreign consumers lose, the latter apparently losing the more of the two consumer groups. Introducing some convexity into either the domestic or foreign demand curve makes the respective consumer group's benefits decline. These results are difficult to compare with those of Just and Hallam because of the different approach and emphasis of the studies, but a striking similarity in the results is that domestic producers are unequivocal beneficiaries of a wheat storage program.

Another type of sensitivity analysis was performed to evaluate the decision rules for storage decisions. The important consideration is not whether the decision rules change considerably under alternative specifications but whether these changes, large or small, have an important impact on the magnitude of the criterion being used. Our test was to calculate optimal decision rules under several specifications other than the standard model, and then use these nonoptimal decision rules in the standard model to determine the change in the criterion from its value under the optimal decision rule; this change is called opportunity loss.

The alternative specifications were linear supply, nonlinear foreign demand, static foreign demand, and three different price elasticities for foreign demand, −0.5, −4.0, and −6.0. These first three specifications are the same as described in reference to the analysis on distribution. Results of the analysis are reported in table 5. These opportunity losses are

Table 4. Distribution of Benefits under Various Specifications

Specification	Criterion	Domestic Producers	Domestic Consumers	Foreign Consumers	Variable Costs of Storage	Value of Criterion[a]
		($ million annually)				
Standard model	Domestic	353	−27	−120	26	300
	World	327	−22	−95	21	189
Linear supply	Domestic	358	−27	−120	26	305
	World	332	−22	−95	21	194
Nonlinear domestic demand	Domestic	306	−101	−120	34	171
	World	283	−91	−95	28	69
Nonlinear foreign demand	Domestic	339	−23	−226	26	290
	World	314	−18	−204	21	71
Static foreign demand	Domestic	489	−28	−184	27	434
	World	439	−25	−165	22	227

Note: Values are for an increase in storage capacity from 1.0 billion to 2.0 billion bushels and an initial state of 3.2 billion bushels of wheat stocks and a price of $3.00.

[a] The domestic criterion is the sum of columns 1 and 2 minus column 4; the world criterion is the sum of columns 1, 2, and 3 minus column 4.

Table 5. Estimated Opportunity Losses in the Sensitivity Analysis

"Erroneous" Specification	Annual Amortized Losses: Domestic Criterion	Annual Amortized Losses: World Criterion
	---- ($ million) ----	
Linear supply	0.0	0.0
Nonlinear export demand	1.1	0.7
Static foreign demand	14.9	18.5
Alternative price elasticities in foreign demand:		
−0.5	81.6	137.0
−4.0	7.7	2.6
−6.0	19.6	15.7

put in perspective by relating them to the gains from storage given in table 4 under the standard model, i.e., $300 million and $190 million for the domestic and world criterion, respectively.

Obviously, the cost is very high of using the optimal decision rule under an assumed elasticity of −0.5, when it is actually −2.5. The decision rule in the inelastic case, −0.5, tends to hold export levels constant across the two state variables of stocks and price, particularly across levels of stocks. For example, under the world criterion, exports are 650 million and 850 million bushels with probabilities 0.29 and 0.71 in the limiting probability vector; other export levels occur with essentially zero probability. As would be expected, the dispersion on price is substantially greater under this kind of decision rule compared to the optimal rule in table 3.

The other misspecifications in table 5 produce decision rules which are "reasonably good" when applied to the standard model. It would appear that a good decision rule can be obtained if we can estimate the price elasticity of foreign demand with even modest precision. If the "true" elasticity is somewhere between −1.50 and −6.0, the decision rule from the standard model is probably near optimal.

We have become somewhat skeptical of the autoregressive price relationship in foreign demand; the reasons are both logical and empirical from experience in the application (see footnote 2, for the logical basis). The results in table 5 showing the opportunity losses of using the static foreign demand specification suggest that the value of information elicited by the autoregressive model is rather nominal, $15 million and $18 million under the domestic and world criteria, respectively. Therefore, we reversed the sensitivity analysis by calculating the opportunity loss from using the decision rule in the standard (autoregressive) model in the static foreign demand model, assuming the latter is the "true" model. These opportunity losses are $75 million and $99 million annually in the domestic and world models, respectively. These results suggest a considerably higher risk associated with assuming the autoregressive as opposed to the static specification. As would be expected, the decision rule associated with the static foreign demand is much less responsive to the price state variable and nearly identical with respect to wheat stocks when compared to the decision rule of the autoregressive model reported in table 3.

Summary and Conclusions

An econometric study of the U.S. wheat industry was made to provide empirical measures to use in a stochastic sequential decision model for wheat storage. The empirical results suggest that present storage capacity which might be identified with wheat is substantially in excess of what can be justified economically. The marginal value of capacity beyond 2.5 billion bushels is near zero even when fixed costs are ignored.

U.S. wheat producers are clearly the beneficiaries of a storage program, while both domestic and foreign consumers experience losses, the latter losing more than the former. Although the curvature of demand and supply equations and the structure of the disturbances have an impact on the benefits of the various groups, the qualitative results of who benefits and loses were not changed by any of the alternative specifications considered.

The method used to incorporate the suppressed state variables in an approximate way seemed to work well and increased expected net benefits by nearly $50 million per year under the domestic criterion and $14 million under the world criterion when initial conditions were those of 1976.

In retrospect, the autoregressive price relationship used in the foreign demand equation probably should be replaced with a static equation, even though less information might be used in the decision process. Additional re-

search is being done to evaluate the choice between these two specifications.

Agricultural Comparative Advantage under International Price Uncertainty: The Case of Senegal

Cathy L. Jabara and Robert L. Thompson

This study draws upon recent theoretical contributions which have introduced uncertainty into trade theory to examine empirically the implications of international price uncertainty for agricultural comparative advantage in a small open economy assuming risk-adverse policy makers. Utilizing a price endogenous, linear programming model developed for Senegal, it is shown that Senegal's comparative advantage in the production of peanuts and comparative disadvantage in the production of cereals is less clearcut when international price risk is considered. The results suggest a trade strategy of less specialization in peanuts and greater self-sufficiency in cereals may be superior to free trade.

Key words: agricultural trade, comparative advantage, international trade policy, risk, sectoral programming models, Senegal.

The traditional theory of comparative advantage demonstrates that if every country specialized in the production and export of goods in which another country is a relatively lower cost producer, both global welfare and the welfare of each trading country would be maximized.[1] This implies that free, undistorted international trade is the first best policy for all countries to follow. However, this implication, which is derived under the assumption of perfect certainty, applies only to small trading countries which cannot influence the world market price by their individual actions. The optimum tariff argument demonstrates that a large trading country can increase its own welfare, albeit at the expense of the rest of the world, by distorting domestic prices away from the international terms of trade (Johnson). Under the assumption of perfect certainty, it is demonstrated that the optimum tariff rate for a small country is zero. However, agricultural trade is characterized by two forms of uncertainty. First, there are climatic inputs in the agricultural production process which are stochastic and not under the farmers' control. Moreover, future international prices are uncertain, known at best in a probabilistic sense.

Due to uncertainty which arises in international markets for agricultural commodities, many countries, especially LDCs, have become increasingly reluctant to accept the logic of comparative advantage and follow a free trade policy. Because prices of imported food grains are uncertain, many countries have adopted policies to distort internal prices away from the international terms of trade to increase their self-sufficiency ratios in food production. In addition, these countries have advocated international commodity programs to stabilize prices of internationally traded agricultural commodities in international fora,

Thompson is an associate professor in the Department of Agricultural Economics at Purdue University, on leave with the U.S. Department of Agriculture.

Journal Paper No. 7923, Indiana Agricultural Experiment Station.

This paper reports part of the results of the senior author's Ph.D. thesis research (Jabara), carried out under U.S. Agency for International Development contract No. AFR-C-1257 with Purdue University and completed prior to her employment by the USDA. The views expressed and conclusions reached are solely those of the authors and do not necessarily reflect those of the U.S. Government.

The authors acknowledge the helpful criticisms and comments received from D. A. Bessler, S. C. Hu, M. A. Martin, B. A. McCarl, W. H. M. Morris, G. R. Rodriguez, G. E. Schuh, T. K. White, and one anonymous *Journal* referee. However, the authors alone are responsible for any remaining errors or deficiencies.

[1] In addition to its normative implications, the theory also has a positive aspect. If global welfare is maximized, each country will specialize in and export those goods in which it is a relatively low-cost producer and import those goods in which other countries are relatively lower cost producers.

such as UNCTAD-IV and the North-South Dialogue. It appears that uncertainty in international markets has become an important criterion in formulating trade policy.

Recently, several theoretical contributions in the international trade literature have examined the validity of the basic theorems of international trade under both international price and production technology uncertainty. (See Pomeroy for a review of this literature.) However, with the exception of one early study by Brainard and Cooper which examines the possibilities of export and import diversification for less developed countries in a mean-variance portfolio framework, there exist no other empirical studies which examine the implications of uncertainty for international trade policy known to the authors. Whereas Brainard and Cooper assumed that international price uncertainty was a sufficient argument for diversification, this study examines whether diversification is desirable from an economic point of view.

The principal objective of this study is to draw upon the recent theoretical contributions that have introduced uncertainty into trade theory in order to examine empirically the implications of international price uncertainty for agricultural production, consumption, and trade of a small, open economy. Specifically, the study takes as its conception of comparative advantage that mix of traded products at which expected welfare (or expected real income) is at a maximum. Under perfect certainty, and with no externalities or domestic distortions, this is that output bundle observed under free trade. The Domestic Resource Cost (DRC) methodology, which has often been employed to measure empirically comparative advantage (e.g., Pearson and Meyer), attempts to correct for domestic distortions. In this paper it is shown that under risk aversion, the expected utility-maximizing output bundle is not that generated under free trade even after correcting for domestic distortions; rather, expected utility is maximized at that output bundle which is produced when domestic prices are distorted away from the international terms of trade by the subjective cost associated with the international price uncertainty. To illustrate empirically the effect of international price uncertainty on agricultural comparative advantage, a modification of the DRC methodology is utilized here within a multiproduct linear programming framework. Bruno suggested using economy-wide programming models to measure comparative advantage. This study follows the approach of Duloy and Norton (pp. 382–86) in the use of an agricultural sectoral model for measurement of comparative advantage. Unlike the latter, this study corrects for economy-wide price distortions, e.g., through the shadow price of foreign exchange. For reasons listed in the text, least-cost spatial equilibrium models like that of Mandell and Tweeten, using financial prices rather than shadow prices of factors and foreign exchange, do not correctly estimate comparative advantage. International price risk is introduced into the objective function of the model in a manner similar to that suggested by Hazell and Scandizzo for income risk at the farm level.

Senegal, a small, open economy with one dominant export, peanut products, and one dominant import product, cereals, was chosen as the case study. Traditionally, Senegal has exported peanuts and the derivative products, oil and meal, in exchange for cereals. A number of observers have argued that this policy was consistent with Senegal's comparative advantage (e.g., CILSS). Peanut production in Senegal typically has averaged about 50% of the country's total agricultural production, and foreign exchange earnings from peanut products have averaged about 40%–50% of export earnings (Dione). At the same time, imports of cereal grains, rice, wheat, millet, and corn constitute about 35% of domestic consumption of these cereals and 52% of the value of foreign exchange earnings from peanuts.

In recent years, however, policy makers in Senegal have promoted a policy of substitution of domestic production for imports of cereals, at the expense of peanut production (République de Sénégal, Ministère du Plan). The empirical analysis focuses on the question of whether this recent change in trade strategy of Senegal is consistent with an extended concept of comparative advantage which explicitly recognizes the subjective costs (assuming risk aversion) associated with international price uncertainty.

Conceptual Framework

In this section, a simple two-sector general equilibrium model is employed to demonstrate the implications of international price uncertainty for trade policy in a small, open econ-

omy. Under the assumptions of perfect certainty, profit maximization, full employment of factors of production, and absence of externalities and domestic distortions, the optimum pattern of trade is determined by the point at which the international terms of trade equals the marginal rate of transformation between the two commodities. The country is said to have a comparative advantage in the good exported and a comparative disadvantage in the good imported *vis-à-vis* the rest of the world. Any departure from free trade will lower the welfare of the country.

To illustrate, assume that the agricultural sector of Senegal produces two commodity aggregates, peanuts (X) and cereals (Y). The production frontier for the sector is defined as

$$(1) \qquad Y_p = F(X_p),\ F' < 0,\ F'' < 0,$$

where $F'(X_p)$ represents the marginal, domestic opportunity cost of peanut production, X_p, in terms of cereal production, Y_p. The country can exchange peanuts for cereals on the international market at a price ratio, $P = P_x/P_y$, which is exogenously given (small country assumption).

Assuming balance of payments equilibrium,[2] production and consumption are linked through trade by the following relationships:

$$(2) \qquad \begin{aligned} X_c &= X_p - X_e \\ Y_c &= F(X_p) + PX_e, \end{aligned}$$

where the subscripts c refer to consumption, p to production, and e to net exports (imports if $X_e < 0$).

The objective of the country is to maximize its welfare, U, as derived from consumption of X and Y:

$$(3) \qquad U = U(X_c, Y_c),\ U' > 0,$$

where U is the welfare function for Senegal as perceived by its planners (Feder, Just, Schmitz). Under perfect certainty, the optimum point of production occurs where the terms of trade equal the marginal rate of transformation $P = -F'(X_p)$. That is, no policy intervention which distorts P can improve the welfare of the population.

To examine the implications of uncertainty in international prices, the model is modified by allowing P to be a random variable with mean $E[P] = \bar{P}$. Because export and import commodities are largely marketed through government marketing agencies which in effect administer internal prices, as in many LDCs, the risk in international prices is assumed to be perceived largely by the planners or policy makers in Senegal. It is assumed that planners in Senegal attempt to maximize expected utility, $E[U]$, from consumption of X and Y. That mix of products traded when expected utility is at a maximum is taken here to define the country's comparative advantage.

Specifically, the country seeks to maximize

$$(4) \qquad E[U(X_c, Y_c)],$$

subject to

$$X_c - X_p + X_e = 0,\ Y_c - Y_p - PX_e = 0.$$

The first-order conditions for an interior solution are[3]

$$(5) \qquad \frac{\partial E[U]}{\partial X_p} = E[U_1] + F'E[U_2] = 0,$$

$$(6) \qquad \frac{\partial E[U]}{\partial X_e} = -E[U_1] + E[U_2P] = 0,$$

where $U_1 = \dfrac{\partial U}{\partial X_c}$ and $U_2 = \dfrac{\partial U}{\partial Y_c}$. Rearranging (5) and substituting into (6), and noting that $E[U_2P] = E[U_2]\bar{P} + \text{cov}[U_2P]$ yields

$$(7) \qquad \bar{P} + \frac{\text{cov}[U_2P]}{E[U_2]} = -F'(X_p),^4$$

where $\text{cov}[U_2P]/E[U_2]$ can be interpreted as the subjective cost associated with the uncertainty in international prices. In order to make the comparison with the certainty case meaningful, it is assumed that $P = \bar{P}$ in the certainty case. Thus, it is evident that $\bar{P} \gtreqless -F'(X_p)$ according to whether $\text{cov}[U_2P] \lesseqgtr 0$.

The sign of the covariance term depends upon the loss function or risk associated with uncertainty in international prices as well as upon the relationship between U_2 and P.[5] Assuming that $X_e > 0$ (Senegal is a net exporter of peanuts), and policy makers in Senegal are risk-averse, the covariance of U_2 and P is negative. Similarly, if policy makers are risk lovers, the covariance will be positive. With

[2] This assumption is relaxed in the empirical model which follows.

[3] The second order conditions must also hold, i.e., the Hessian matrix of second order partial derivatives must be negative definite.

[4] A similar condition was obtained by Hazell and Scandizzo in their analysis of the effect of risk on producer decision making.

[5] Assuming the utility function satisfies the assumptions of von Neumann-Morgenstern utility theory, if $U_{11} < 0$, the policy makers or planners are risk-averse; if $U_{11} = 0$, they are risk-neutral; and if $U_{11} > 0$, they are risk lovers.

risk neutral policy makers, the covariance term is equal to zero.

The results indicate that under risk aversion $\bar{P} > -F'(X_p)$. That is, the expected utility-maximizing policy for a small economy confronting international price risk is not a free trade policy with the international terms of trade reflected in undistorted domestic prices. Rather, equation (7) shows that the optimum trade policy is for the domestic terms of trade to be set equal to the expected international price ratio plus the subjective risk cost. In Senegal, the internal price of peanuts relative to cereals should be set lower than the world price ratio to move producers to a point on the production possibility frontier corresponding to a greater production of cereals (less imports) and a lower production of peanuts (and exports) than in the certainty case. The distortion should be greater, the greater the risk aversion of the policy makers. To define comparative advantage when there exists international price uncertainty, the net returns from production of the export product should be lowered by the subjective cost of risk associated with variation in its export price.[6] This, in effect, shifts the excess demand schedule of the rest of the world confronted by Senegal downwards by the subjective cost.

Similarly, if P and X_e are defined in terms of cereals such that $X_e < 0$ (Senegal is a net importer of cereals) and there is uncertainty in the international price of cereals, $\mathrm{cov}[U_2P] > 0$ and $\bar{P} < -F'(X_p)$, with risk aversion. In this case, Senegal would move to a point corresponding to a larger production of cereals (less imports) than in the certainty case. This result implies that, for the measurement of comparative advantage, the international price at which the commodity can be imported should be augmented by the subjective risk cost associated with uncertainty in its price.

Empirical Model

The empirical model is first developed and validated under observed prices in Senegal and then modified appropriately to carry out the comparative advantage analysis in later sections. The specification of the basic empirical model draws upon the work of Duloy and Norton, Egbert and Kim, and others in the formulation of price endogenous, linear programming, agricultural sectoral models. (See McCarl and Spreen for a survey of this literature.) The linear programming model developed for Senegal includes regional agricultural production activities, regional demand functions and regional processing activities for agricultural products, transport activities, and import and export activities. The export commodities in the model are peanuts and cotton; import commodities include rice, millet, wheat, and corn. (For more details, see Jabara, pp. 63–92.)

A regional specification of the agricultural sector model of Senegal was formulated in order to take into account the effect of internal transport costs from production regions in the interior to the port of Dakar, the destination for the bulk of the imports into Senegal. Area planted as well as production of agricultural commodities in Senegal varies by region due to the differences in rainfall. The regions in the model are listed and the salient characteristics of each are summarized in table 1.

Production activities for each region in the model were specified to differ by level of fertilizer use and type of mechanization. Three degrees of mechanization were specified for each crop: manual, horse-drawn traction, and ox-drawn traction. Five alternative levels of fertilizer use were included for both horse-drawn and ox-drawn technologies for millet and peanuts. Irrigated crop activities using tractor power also were specified for the Fleuve.

For each production activity, standard inputs of labor and services of machinery per draft animal were defined for the crop year. Labor requirements were expressed in terms of man-days, and services of draft animals were expressed in animal-days for five periods of the agricultural year. Chemicals and extension costs were expressed in terms of CFA[7] per hectare and fertilizers in terms of kilograms of nitrogen-phosphorus-potassium (NPK) fertilizer mixture per hectare.

The resources constrained in the model include land, processing capacity, and fertilizer availability. Land was classified by region as upland, swamp, flood recession, or irrigated. Land planted to cotton, improved rice, and

[6] The same analysis applies to the case of uncertainty in production technology, where the uncertainty is reflected in the effects of weather, disease, pests, etc. In this case, the domestic cost of producing the export crop is increased by the subjective risk cost associated with domestic production uncertainty. See Jabara, chap. 2, for details.

[7] The CFA is the currency of Senegal. It is tied to the French franc at a rate of exchange of 50 CFA per French franc.

Table 1. Characteristics of Regions in Senegal Agricultural Model

Region	Total Land Area	Principal Crops	Population[c]	Annual Rainfall[d]
	(1,000 ha.)		(1,000)	(mm.)
Northern[a] Peanut Basin	4,015	millet, sorghum, peanuts	1,131	400–800
Southern Peanut Basin (Sine Saloum)	2,394	millet, sorghum, peanuts, cotton, corn	1,014	800–1,000
Fleuve	4,413	peanuts, corn, millet, sorghum, irrigated rice	532	200–400
Casamance	2,835	rice, cotton, corn, peanuts, millet, sorghum	741	1,000–1,500
Senegal Oriental	5,960	rice, cotton, corn, millet, sorghum, peanuts	288	800–1,000
Cap Vert[b]	—	—	990	—

[a] Refers to administrative regions of Thies and Diourbel.
[b] This region comprises the Dakar area, which is primarily urban.
[c] Source: Vth Plan. Population figures are for 1976.
[d] Rainfall in Senegal is concentrated largely in the months from June–November.

corn in the Southern Peanut Basin was constrained at the levels for 1975/76 because the production of these crops is controlled by government programs. Fertilizer access was also constrained in the model because it is available only to farmers who are members of the cooperatives.

Two types of labor were supplied in the model by region: domestic family labor and *navetanes*. The *navetanes* are seasonal laborers who come to Senegal from Mali or Guinea Bissau and remain for the duration of the cropping season (May to November). Both types of labor were assumed to be supplied at a constant cost charged to the objective function (i.e., infinitely elastic supply assumed). For *navetanes* this charge is the yield of a hectare of land planted in peanuts times the producer price, plus food for the cropping season. For family labor, one-half of the market wage rate per man-day times the number of man-days supplied in each year was entered into the objective function as a reservation wage.

Separate demand functions for all products were specified for the urban and rural populace. About 80% of domestic production of cereals is consumed on the farm in Senegal. However, due to a lack of data with which to estimate on-farm demand functions, home consumption was taken as exogenously given at observed levels. For urban consumers, downward sloping demand functions were estimated.

Econometric estimates of urban demand functions for millet, rice, and peanut oil were made by Jabara. These price elasticities, estimated through a constant elasticity (log-linear) formulation, were -1.25 for peanut oil, -0.75 for rice, and -0.48 for millet. Price elasticities of demand for maize and wheat could not be estimated due to data deficiencies. However, because the demand characteristics of the cereals are similar in Senegal, the same estimated price elasticity was used for wheat and rice. Similarly, the same estimated price elasticity was used for millet and maize. Cross-price elasticities were not included because they could not be estimated and there exist no estimates known to the authors. It was assumed that the urban price and income elasticities of demand for each cereal are the same in all regions. A price elasticity of -0.3, obtained for the Ivory Coast, was used for cotton (Vaurs, Goreux, Condos).

The objective function of the model was specified to simulate a competitive market equilibrium where price equals marginal cost for each production activity. The objective function, which is maximized, equals the sum of the areas under the domestic demand schedules, plus the value of exports, less the cost of imports, processing, input supply, and transport. (The cost associated with international price risk is introduced later in the comparative advantage under risk section.) The objective function was specified under the behavioral assumption that the micro units which comprise the Senegalese agricultural sector are profit maximizers.

Model Validation

The solution values for area planted, production, imports, and exports in the model are presented in table 2. For the purpose of validation, table 2 compares the model solutions for these variables to observed, annual values for 1973/74–1975/76. For brevity, the regional solutions are aggregated into country totals for Senegal. (See Jabara, pp. 96–101 for regional detail.) All prices in this specification of the model are the observed prices in 1975/76. These are the exogenously given world prices (small country assumption) as distorted by existing policy interventions in Senegal. These distortions include export taxes on peanut products as well as a consumer tax on imported rice which acts to make domestic production of rice more competitive with imports in certain regions of the country. The producer price of irrigated rice is also subsidized in the Fleuve region.

In general, the basic specification of the model appears to replicate, reasonably, observed conditions in Senegal. For crop production and area planted, the percentage deviations of the model solutions from the observed values are quite small. The largest deviation is for cotton production. Export volumes generated by the model are overstated in every case. This result is due, in part, to the constraint that at least 80% of peanut production would be marketed by farmers. The remaining 20% represents losses, seed, home consumption, and sales to the unofficial market. The actual percentage may be less.[8]

A lower bound was imposed on millet imports at the level of imports for 1975/76 because, at the prices in the model, it is profitable to supply all domestic millet consumption from domestic production. In reality, Senegal imports small quantities due to internal marketing problems.

Comparative Advantage under Price Certainty

Chenery has argued that the optimum pattern of trade is defined by comparing the opportunity cost of producing a given commodity with the price at which the commodity can be exported or imported, after correcting for any price distortions in the economy. In this case, the relevant cost of production of each commodity equals the value of the factors of production used to produce it, as measured by shadow prices, which reflect the true scarcity values of the factors to the economy. The essence of the DRC method of analysis of comparative advantage is to compare the domestic cost of production (measured by shadow prices) with the international price at which the commodity is exported or imported (Pearson and Meyer).

The DRC approach tends to be partial, and it ignores substitution effects in production. In contrast, the approach employed here is to adapt the multicommodity programming model described in the previous section to analyze agricultural comparative advantage in Senegal. The programming model, in whose solution all commodities are produced in their relatively least-cost location, represents an improvement upon the Domestic Resource Cost technique by explicitly taking account of factor substitution.

In order to analyze agricultural comparative advantage in Senegal, all prices in the basic model were adjusted to correct for domestic price distortions which arise from policies of the Senegalese government. In order to cor-

[8] This discrepancy is partly due to the fact that the data on production and exports come from two different sources which are not necessarily consistent. International trade statistics are readily available in Senegal, and the quality of the data is quite good. Production data are more difficult to obtain, and the information is of a lower quality.

Table 2. Senegal Agricultural Sector Model Validation Results, 1975/76

	Model Results	Observed Value	Percentage Error
Area planted	(1,000 Hectares)		
Peanuts	1,105.7	1,120.2	−1.3
Millet	1,074.3	1,047.5	2.5
Maize	61.5	57.1	7.6
Cotton	39.2	41.1	−4.6
Rice	87.8	82.4	6.6
Production	(1,000 Metric Tons)		
Peanuts	1,046.1	1,044.0	0.2
Millet	653.2	661.4	−1.2
Maize	51.8	48.7	6.4
Cotton	46.8	37.5	24.6
Rice	117.2	123.8	−5.3
Exports	(1,000 Metric Tons)		
Peanut oil (crude)	200.3	153.6	30.3
Peanut oil (refined)	36.8	30.0	22.5
Peanut meal	334.7	283.1	18.2
Raw cotton	12.6	7.9	59.9
Imports	(1,000 Metric Tons)		
Rice	161.6	170.9	−5.4
Wheat	90.3	99.4	−9.1
Maize	4.1	6.1	−32.0
Millet	6.0	6.0	0.0

rect for these distortions, all material inputs of production were valued at the supply cost to Senegal, adjusted for taxes. The foreign exchange component of the cost of material inputs, as well as the c.i.f. and FOB prices of imports and exports, respectively, were converted into domestic currency units by the shadow price of foreign exchange. The shadow price estimated for this study indicates that the CFA was overvalued by 13%. Capital expenditures were also evaluated at the shadow interest rate for Senegal. These latter shadow prices, for foreign exchange and capital, were assumed to be economy-wide estimates of the appropriate values. Shadow prices for land and labor were generated endogenously by the model. Activities for interregional trade were also included in the comparative advantage formulation (see Jabara, pp. 110–22, for details).

The results of the comparative advantage analysis under price certainty are presented in table 3 and compared to the base case from table 2. The results of table 3 indicate that at the "adjusted" prices, Senegal has a comparative advantage in the production and export of peanuts and a comparative disadvantage in the production of cereals. In the comparative advantage solution, the area planted to peanuts increases by 11% over the base model result. Area planted in all crops, as well as production of cereals, declines relative to the base solution. As a result of these changes, exports of peanuts and imports of cereals increase relative to the base model. Thus, in the comparative advantage solution, Senegal moves to a point on its production frontier which is more specialized in the production and export of peanuts than in the base case in which prices are distorted.

The relatively small magnitudes of the changes in production and trade in table 3 are due to the assumption made in the model that imports supply only urban areas and that the farm population produces all of its own consumption. However, the direction of the change is the important indicator of the direction of comparative advantage for Senegal with undistorted prices.

The largest change is in the area planted and production of rice, which decreases by about 22%. This change reflects the comparative disadvantage of Senegal in the production of rice and the relatively large urban demand for rice.

Table 3. Model Solutions for Comparative Advantage Case, Compared to the Base Model, Senegal, 1975/76

Activity	Comparative Advantage Solution	Base Solution	Percent Change
Area Planted	----- (1,000 Hectares) -----		
Peanuts	1,224.7	1,105.7	11.0
Millet	970.0	1,074.3	−9.7
Maize	60.6	61.5	−1.4
Cotton	36.8	39.2	−6.2
Rice	68.9	87.8	−21.5
Production	---- (1,000 Metric Tons) ----		
Peanuts	1,152.3	1,046.1	10.1
Millet	599.3	653.2	−8.2
Maize	50.5	51.9	−8.2
Cotton	46.9	46.8	0.3
Rice	91.0	117.2	−22.4
Exports	---- (1,000 Metric Tons) ----		
Peanut oil (crude)	228.2	200.3	13.9
Peanut oil (refined)	36.8	36.8	0.0
Peanut meal	368.0	334.7	10.0
Cotton	13.4	12.6	6.5
Imports	---- (1,000 Metric Tons) ----		
Rice	214.3	161.6	32.6
Wheat	90.3	90.3	0.0
Maize	5.2	4.1	27.0
Millet	53.5	6.0	790.9

Comparative Advantage under Price Uncertainty

The above analysis of comparative advantage assumes perfect certainty in international prices which are reflected undistorted into the Senegalese economy. However, as illustrated in table 4, which presents the means, standard deviations, and coefficients of variation for the traded crops in Senegal, it is evident that there exists considerable uncertainty in the international prices confronted by Senegal. This table suggests that rice, which has the highest coefficient of variation of all of the commodities, is the riskiest commodity to import in terms of price variability. The coefficients of variation for peanut products are also high relative to the coefficients of variation of other cereals (except rice) and cotton prices. Based upon this evidence and with the additional assumption of risk aversion of economic policy makers, a trade strategy based upon exports of peanut products in exchange for rice may not be the most desirable trade strategy for Senegal.

Hazell and Scandizzo have shown that when risk is included on the supply side in the

Table 4. Means, Standard Deviations and Coefficients of Variation for International Prices of Traded Commodities, Senegal, 1968–1976

Commodity	Mean Price	Standard Deviation of Price[a]	Coefficient of Variation[b]
Imports	----	(1,000 CFA/ton)	----
Millet	22.6	3.9	.17
Wheat	28.5	5.4	.19
Maize	24.7	2.5	.10
Rice	43.0	18.1	.42
Exports	----	(1,000 CFA/ton)	----
Peanut oil (crude)	118.7	40.6	.34
Peanut oil (refined)	135.7	37.2	.27
Peanut meal	27.1	6.2	.23
Peanuts	76.7	20.9	.27
Cotton	214.3	37.4	.17

[a] Estimated as the standard error of the estimate from a linear regression of the form $Y = a + bt$ where Y = international price, t = time, and a and b are the estimated regression coefficients.
[b] The coefficients of variation in this table may overstate the uncertainty in international prices due to unusually large price increases in 1973.

objective function of such a sector model, the marginal cost schedule for risky activities is shifted to the left by the subjective cost of risk associated with the activity. In the international price uncertainty context, this implies that the excess supply schedule of the rest of the world is shifted upward, i.e., the cost of importation is increased by the subjective cost of risk associated with variation in import prices. On the export side, international price risk implies that the returns to exporting the product are decreased by the subjective cost associated with variation in export prices.

Risk is incorporated into the Senegal agricultural sector model through an $(E, \phi\sigma)$ utility formulation (Hazell and Scandizzo, Simmons and Pomerada).[9] In the Hazell and Scandizzo formulation, the relevant decision makers are taken to be the farmers who base their production decisions on expected income less the subjective cost of risk associated with the income-producing activity. In this present application, the relevant decision makers are the policy makers in Senegal who administer domestic prices and determine how far to distort internal prices away from the international terms of trade. The expectations operator, E, refers to expected world price, σ to the standard deviation of that price, and ϕ is the subjective risk coefficient, which measures the degree of risk aversion of the decision makers.

With the additional assumptions of risk aversion and international price variability, the microunits which comprise the sector are assumed to produce where price received equals marginal cost. However, the internal prices which the producers face are lowered (raised) by the policy makers relative to international prices by the cost of risk that they associate with export (import) prices. This approach assumes that policy makers can effectively fix domestic prices to reflect the perceived cost of risk to the economy. In Senegal this is accomplished by fixing the price at which the official marketing agency, *Office Nationale de Coopération et d'Assistance pour le Développement* (ONCAD) purchases peanuts and cereals. Although there exists some trading on unofficial markets, especially in the case of millet and maize, the official prices serve as guaranteed prices and unofficial prices tend to align themselves around these levels (*Société d'Études de Développement Nationale*).

The measure of variability in international prices used in the model was the standard deviation as estimated from the mean absolute deviation (Hazell). Separate standard deviations were estimated for the portfolios of export prices and import prices. Following Brainard and Cooper, it was assumed that planners would prefer export prices to be negatively correlated with each other and import prices to be negatively correlated with each other. To reflect this in the model, separate measures of import and export price variability had to be included.

The standard deviations of import and export prices during 1968–76, the period for which data were available, were calculated on FOB prices for exports and c.i.f. prices for imports in Senegal. The data were detrended using linear regressions of prices against time, in order to account for systematic variations in international prices.

The risk coefficient, ϕ, is assumed to be a suitable average of the subjective risk cost across traded commodities as perceived by policy makers in Senegal. In principle, the planners' utility function could have been elicited and the value of ϕ empirically estimated (Anderson, Dillon, Hardaker, chap. 4). However, lacking resources for this purpose, alternative solutions of the model were obtained by parametrically varying ϕ from 0 to

[9] Simmons and Pomerada used the standard deviation, σ, as the measure of uncertainty, whereas Hazell and Scandizzo suggested the use of the variance σ^2.

2.5, the most common values used in the literature (Hazell et al.).

Table 5 gives the model results for analysis of comparative advantage under price uncertainty for Senegal. At a value of $\phi = 0$, the comparative advantage solution presented in table 3 is obtained. Larger values of ϕ represent greater degrees of risk aversion of the policy makers in Senegal. While the value of ϕ was not estimated empirically, the larger values of ϕ appear to be more consistent with the stated objectives of policy makers in Senegal.

The results of table 5 suggest that Senegal's comparative advantage in peanuts *vis-à-vis* cereals is less clear-cut when uncertainty in international prices and risk aversion are introduced. As the degree of risk aversion, as measured by ϕ, increases, production and exports of peanuts decrease relative to the comparative advantage ($\phi = 0$) case. At the same time, production of millet, maize, and rice increase relative to the comparative advantage case. Imports of all cereals decrease. The decrease in wheat imports is relatively smaller because Senegal, at present, produces virtually no wheat. The decrease in imports is caused by the subjective price increase associated with uncertainty in the international price of wheat.

At the higher value of ϕ in table 5, Senegal becomes self-sufficient in millet and maize in the interior of the country, but imports remain the least-cost source of supply to the port region, the Cap Vert. This result indicates that even with international price uncertainty, it remains socially profitable for Senegal to import cereals for consumption near the port because of high internal marketing costs. Imports remain the least cost source of supply of rice to all regions of the country.

Table 5. Comparative Advantage Solutions under International Price Uncertainty, Senegal

	Degree of Risk Aversion		
Commodity	$\phi = 0.5$	$\phi = 1.5$	$\phi = 2.5$
Imports		(1,000 Metric Tons)	
Rice	212.8	197.7	183.6
Wheat	90.3	90.3	88.3
Millet	45.4	25.9	16.0
Maize	4.7	4.1	3.5
Exports		(1,000 Metric Tons)	
Peanut oil (crude)	215.2	188.1	183.4
Peanut meal	352.5	320.1	314.5
Peanut oil (refined)	36.8	26.8	26.8
Cotton	13.3	12.9	12.9
Area planted		(1,000 Hectares)	
Peanuts	1,208.7	1,087.0	1,070.7
Millet	984.4	1,105.0	1,117.7
Maize	36.8	35.7	35.7
Cotton	60.3	61.8	61.5
Rice	68.9	71.3	74.8

The largest percentage increase in area planted as ϕ increases is in millet production. This increase in millet production is largely caused by the decrease in profitability of peanuts relative to millet associated with the greater uncertainty in the international price of peanut products. Thus, risk, in effect, distorts the domestic perception of the international terms of trade of peanuts in terms of millet towards a price ratio that is more favorable for millet and less favorable for peanuts.

Although international rice prices have the largest coefficient of variation, the increase in rice production is not as large as for millet as ϕ increases. This result is due to the large comparative disadvantage of Senegal in rice production when evaluated at world prices. Maize production does not increase to any large extent in the international price risk solutions because at $\phi = 0$, Senegal is basically self-sufficient in maize production with the exception of the region near the port which imports maize.

In the larger study (Jabara), domestic yield, as well as international price uncertainty, were introduced into the comparative advantage analysis. These results indicated that when both sources of uncertainty are considered, the pattern of comparative advantage is less clear cut. Instead, comparative advantage depends upon the relative weights the planners associate with the risk from the different sources. Uncertainty in the domestic yields of all crops in effect shifts their supply schedules upward. Uncertainty in international prices shifts the rest of the world's excess demand schedules for exports downward, and excess supply schedules for imports, upward. Therefore, uncertainty in both yields and world prices of exportable crops works in the same direction to reduce exports, but uncertainty in both yields and world prices of importable crops works in opposite directions. In Senegal, where stated policy promotes import substitution, it appears that policy makers place a lower weight on yield uncertainty for import substitute crops than on international price uncertainty.

Conclusions and Policy Implications

This study has attempted to analyze empirically the comparative advantage of a small,

open economy under the assumption of aversion of economic policy makers to international price risk. The results of the empirical analysis, which includes international price risk, show that a country may be better off at a more diversified position than would be prescribed by a conventional comparative cost analysis. That is, free, undistorted trade may not be the first best policy for all small countries to follow. Domestic import substitution programs, such as the one pursued by Senegal, may be preferable to free, undistorted trade when risk aversion is taken into account. Such programs may indeed be consistent with a broader concept of comparative advantage which recognizes that risk has a subjective cost.

The results of the analysis also suggest that a small trading country in an uncertain environment can increase welfare by distorting internal prices away from the international terms of trade. In Senegal, policy interventions lower the internal prices of the export products, peanuts and cotton, and raise the internal prices of cereals. The analysis presented here suggests that in the presence of international price uncertainty Senegal was made better off by producing more cereals at the expense of peanuts. Government policies which distort internal prices away from international prices to reflect the cost of risk to the economy, as perceived by policy makers, may be superior to free trade from an economic point of view.

In addition, to the extent that many LDCs act simultaneously to implement import substitution programs, the rest of the world will be made worse off.[10] Moreover, if these countries impose quantitative restrictions or otherwise cut the link between domestic and international prices as suggested here, greater price instability will result in international markets. This suggests that commodity agreements or other schemes designed to stabilize world commodity prices could play an important role in promoting greater international trade among countries as a result of reducing international price uncertainty.

[Received June 1979; revision accepted November 1979.]

[10] It is assumed that the small trading country assumption applies to each LDC individually, i.e., no one country's actions alone can affect the international terms of trade. However, if many LDCs simultaneously impose trade restricting policies, their combined actions would affect world market prices.

Mitigating the Effects of Multicollinearity Using Exact and Stochastic Restrictions: The Case of an Aggregate Agricultural Production Function in Thailand

Ron C. Mittelhammer, Douglas L. Young, Damrongsak Tasanasanta, and John T. Donnelly

Ordinary least squares, exactly restricted OLS, stochastically restricted OLS (mixed estimation), and principal components regression each were used to estimate an aggregate agricultural production function for Thailand for which data were highly multicollinear. Pretest considerations, incorporating alternative risk measures, were addressed in detail for purposes of model evaluation. The final mixed and principal components models generally outperformed OLS in terms of risk and overall reasonableness, mitigating a serious multicollinearity problem and permitting a direct examination of the rate and composition of Thai agricultural output growth.

Key words: biased estimation, multicollinearity, production function, Thailand agriculture.

In recent years econometricians have made substantial progress in developing alternatives to ordinary least squares (OLS) regression techniques that have the potential for mitigating the effects of multicollinearity. These alternatives have included ridge regression (Hoerl and Kennard), principal components regression (Hill, Fomby, Johnson; Mittelhammer and Baritelle; Hill and Fomby), exact linear restrictions (Goldberger), Bayesian econometrics (Zellner), and mixed estimation (Theil and Goldberger). Although these estimating techniques may produce biased estimates, their advocates have demonstrated that they can achieve substantial reductions in mean square errors under appropriate circumstances. The theoretical progress in development of biased alternatives to OLS regression procedures has been accompanied by development of the statistical properties of pretest estimators in regression analysis (Bock, Judge, Yancy; Brook; Wallace).

In spite of the immediate relevance of these theoretical developments to applied economists, there has been relatively little consideration of either biased regression techniques or pretest implications in applied econometric research. Notable exceptions in the agricultural economics literature are the studies by W. Brown, Brown and Beattie, and Moscardi and de Janvry, which used ridge regression to estimate production functions, and the studies of Holloway, Mittelhammer and Price, and Price and Mittelhammer which use the mixed estimator.

The purpose of this paper is to evaluate in an applied study the use of three alternative regression techniques to mitigate the effects of serious multicollinearity and also to discuss the implications of pretest considerations. The techniques are applied to the estimation of an aggregate agricultural production function for Thailand using time-series data from 1950 to 1976 (see Tasanasanta). The alternatives to OLS which are examined include OLS regression with exact linear restrictions, mixed estimation (or regression with stochastic linear restrictions), and principal components regression (PCR). A pretest estimator can be implied in the use of each of the techniques

Ron C. Mittelhammer and Douglas L. Young are assistant agricultural economists and assistant professors in the Department of Agricultural Economics at Washington State University. Damrongsak Tasanasanta was a graduate student and John T. Donnelly is an associate professor in the Department of Economics at Washington State University.

College of Agriculture Research Center Paper No. 5577.

utilized, and pretest considerations are addressed in the discussion that follows.

Aggregate Production Function Estimation and Agricultural Growth Measurement

Attempts to estimate aggregate production functions have been plagued by high correlations among explanatory variables since the pioneering work of Cobb and Douglas five decades ago. Serious multicollinearity typically reduces the precision of parameter estimates to the point where confidence in their signs and magnitudes is very low. Compounding the multicollinearity problem have been efforts to measure technological advance in the aggregate production process by using some function of time as a proxy. Aggregate measures of land, labor, and capital inputs tend to be highly correlated with each other and with time. Murray Brown (p. 112) has cited this problem as a major obstacle to measuring technological progress by directly estimated aggregate production functions.

In the current application, the use of alternative regression techniques to overcome extreme multicollinearity among aggregate input levels and time made possible a more useful decomposition of the sources and rates of growth in real Thai agricultural output during the period 1950–76. The specific objectives of this analysis are twofold: (*a*) to obtain accurate estimates of production elasticities for land, labor, capital, and technology in Thai agriculture in order to decompose 1950–76 agricultural growth between neutral technological progress and increased use of conventional inputs; and (*b*) to test the hypothesis that three government-sponsored economic planning periods between 1961 and 1976 had no discernible impact on the rate of any neutral technological progress in the agricultural sector.

It should be noted that determining the contribution of technological progress to output growth by direct estimation of the underlying aggregate production function has some strong theoretical advantages over the commonly used index number approach pioneered by Solow. (See Nevel for an application of the Solow approach to the U.S. agriculture sector.) Use of the Solow method requires assuming both constant returns to scale and perfectly competitive equilibrium (i.e., all inputs are being paid their marginal value products), but these two strong assumptions can be relaxed if it is possible to estimate the aggregate production function directly. As illustrated in figure 1, the proportionate contribution of neutral technological progress ($\Delta Q_T/\Delta Q$) and of conventional input expansion ($\Delta Q_I/\Delta Q$) can be calculated straightforwardly by decomposing output growth (ΔQ) over t_0 and t_n between a movement along the beginning year production function and the shift between base and ending year production functions.

Thai Agricultural Growth Experience

As the largest sector of the Thai economy, agriculture currently provides one-third of the GDP, 70% of export earnings, and employment for 78% of the total labor force (Ministry of Agriculture and Cooperatives; Sriplung). The critical role of agriculture in generating foreign exchange was accentuated by the marked reduction of capital inflows associated with the withdrawal of American troops during the early 1970s and by continuing deficits in the balance of trade (Ministry of Agriculture and Cooperatives). Within Thailand, the importance of the agricultural sector has been recognized by increased budget allocations over time to the Ministry of Agriculture and Cooperatives and an explicit focus on agriculture in recent government planning periods (Tasanasanta).

In spite of Thailand's generally accepted, promising, agricultural potential, there is a widespread feeling that actual performance has fallen short of that potential. This view is based largely on the observed relatively slow rate of adoption of the new high yielding varieties (HYVs) of rice and the related minimal impact of the "Green Revolution" in Thailand as compared to certain other Asian countries

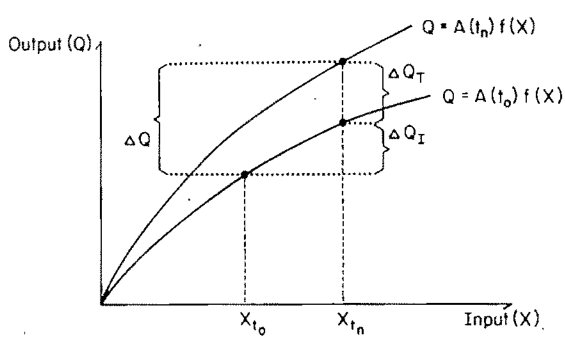

Figure 1. Contributions of neutral technological progress (ΔQ_T) and of input expansion (ΔQ_I) to total growth in output (ΔQ)

(Griffin, pp. 41–43; Myint, chap. 2). This phenomenon has been attributed to both environmental and administrative constraints. First, as is well known, a necessary condition for realizing the yield potential of the HYVs of rice is water control facilities or exceptionally well-distributed rainfall (B. Johnston, pp. 397–80). In Thailand, the lack of flood control facilities has constrained the adoption of the short-stemmed HYVs in the deep-flooding river basins, while inadequate irrigation development has limited adoption in the Central Plains (Griffin; Hsieh and Ruttan). Second, and more generally, in Thailand a scarcity of effective agricultural research and extension resources, together with high input costs, incentive-weakening commodity price policies, and infrastructural and administrative deficiences may have seriously limited the realization of productivity gain potentials in agriculture (Silcock).

In view of these widespread predominantly qualitative speculations on agricultural productivity trends in Thailand, a quantitative examination of the sources and rates of agricultural growth, and the impact of government planning periods on that growth, appeared to be justified.

OLS Model and Results

A variant of the Cobb-Douglas production function which permits a constant rate of neutral technological progress was selected.[1] Upon modification to permit differential productivity growth between government planning periods, the specification became

$$(1)\quad Q = Ae^{t(\alpha_0+\alpha_1D_1+\alpha_2D_2+\alpha_3D_3)}L^{\beta}N^{\gamma}K^{\sigma}e_u,$$

where Q is aggregate agricultural output in billion baht at constant 1956 prices, including crops, livestock, fishery, and forestry output; A is a constant; t is time, 1, 2, . . . , 27; L is land input, harvested acreage in million rai; N is agricultural labor force in million workers; K is agricultural capital in billion baht at constant 1956 prices; D_1 is 1 in 1961–66, 0 elsewhere, representing first government planning period; D_2 is 1 in 1967–71, 0 elsewhere, representing second government planning period; D_3 is 1 in 1972–76, 0 elsewhere, representing third government planning period; and u is the error term.

Given a value of t, the production function is conditionally homogeneous of degree $(\beta + \gamma + \sigma)$ in land, labor, and capital. The time variable $e^{t(\alpha_0+\alpha_1D_1+\alpha_2D_2+\alpha_3D_3)}$, is introduced as a proxy for neutral technological change. The rate of technological progress is $(\partial Q/\partial t)/Q = \alpha_0 + \alpha_1D_1 + \alpha_2D_2 + \alpha_3D_3$.

Taking the natural logarithm of both sides of equation (1), the following estimating equation for the production function was obtained:

$$(2)\quad \ln Q = \ln A + \alpha_0 t + \alpha_1 D_1 t + \alpha_2 D_2 t + \alpha_3 D_3 t + \beta \ln L + \gamma \ln N + \sigma \ln K + u.$$

Examination of the simple and multiple correlations involving regressors in (2) indicated that a serious multicollinearity problem existed. Selected squared multiple correlations are presented in table 1. (See J. Johnston, p. 163, on the usefulness of multiple correlations in detecting multicollinearity.)

Pure estimation of the highly multicollinear model in (2) using ordinary least squares revealed the characteristic symptoms of imprecise estimation of the parameters of the model (see model 1 results in table 2). All but two of the parameter estimates are judged insignificant by the standard t-test at the .05 level of type I error ($t_{.05,\ 19\ df} = 2.093$). The extremely high estimated elasticity on the labor variable which indicates a 3.23% increase in output for a 1% increase in labor seems particularly unreasonable.

A simultaneous test of the hypothesis that all three coefficients associated with the government-planning period dummy variables

Table 1. Selected Multiple Correlations Involving Independent Variables

Dependent Variable	Regressed On	R^2
$\ln L$	$\ln N$, $\ln K$, t	.952
$\ln L$	$\ln N$, $\ln K$, t, D_1t, D_2t, D_3t	.964
$\ln N$	$\ln L$, $\ln K$, t	.995
$\ln N$	$\ln L$, $\ln K$, t, D_1t, D_2t, D_3t	.998
$\ln K$	$\ln L$, $\ln N$, t	.990
$\ln K$	$\ln L$, $\ln N$, t, D_1t, D_2t, D_3t	.998
t	$\ln L$, $\ln N$, $\ln K$	.997
t	$\ln L$, $\ln N$, $\ln K$, D_1t, D_2t, D_3t	.999

[1] The many limitations of the simple Cobb-Douglas form and the assumption of neutral technological progress have been well documented in the literature, e.g., see Murray Brown. However, given the limited adoption of the "Green Revolution" technologies in Thai agriculture, the assumption of neutral technological progress seemed reasonable in this initial investigation. This easily manageable specification also facilitated comparisons of the estimation techniques whose evaluation was a principle objective of this research.

[a] Model 1 is pure ordinary least squares (OLS); model 2 is OLS with exact linear restrictions; model 3 is mixed estimation; model 4 is mixed estimation with exact linear restrictions; model 5 is principal components regression (PCR) (model 7 results in terms of the original variables); model 6 is OLS on principal components and dummy variables; and model 7 is 6 with exact linear restrictions.

[b] Values in parentheses are t-values.

are zero was accomplished using an F-test.[2] The test served a dual purpose in this context. The obvious information provided by the test was a statistical decision regarding the significance of the government-planning periods in affecting Thai agricultural output growth.

The second purpose for the test was to assist in selecting a model that would best meet the study objective of obtaining accurate estimates of production elasticities. It is well known that the restricted least squares estimator has a variance-covariance matrix that is smaller than the variance-covariance matrix of the unrestricted least squares estimator by a positive semidefinite matrix for any linear restrictions on the parameters of a linear model (Goldberger). However, if the restrictions are not true, bias is introduced into the estimates of the parameters of the restricted model. The choice between the restricted and unrestricted estimates then involves the classic tradeoff between decreased variance and increased bias (Wallace, pp. 432–33). In practice, the bias and variance characteristics of an estimator are often combined into various mean-square error measures that are used to assess the accuracy of the estimator. The three measures that appear to have received the most attention in the literature and that are used to assess estimator accuracy in this study are the risk matrix criterion

$$(3)\quad MSE(\hat\beta, \beta) = E[(\hat\beta - \beta)(\hat\beta - \beta)'],$$

and the two quadratic risk functions

$$(4)\quad \rho(\hat\beta, \beta) = E[(\hat\beta - \beta)'(\hat\beta - \beta)], \text{ and}$$

$$(5)\quad \rho(X\hat\beta, X\beta) = E[(X\hat\beta - X\beta)'(X\hat\beta - X\beta)] = E[(\hat\beta - \beta)'X'X(\hat\beta - \beta)]$$

(Wallace, pp. 434–38), where X is the $(n \times k)$ matrix of explanatory variable values, and $\hat\beta$ is an estimator of β.

The risk criteria differ in the parameter space over which risk is measured, and a brief digression into the meanings of the risk measurements as they pertain to estimator comparisons will be useful. With reference to the risk matrix criterion (3), an estimator $\hat\beta$ is said to be strong mean square error ($SMSE$) superior to an estimator $\tilde\beta$ iff $MSE(\tilde\beta, \beta)$ exceeds $MSE(\beta, \beta)$ by a positive semidefinite matrix. Superiority of $\hat\beta$ in $SMSE$ thus implies that the mean square error of any linear combination of the entries in $\hat\beta$ is less than or at most equal to the mean square error of the corresponding linear combination of the entries in $\tilde\beta$. Estimator superiority is judged over the parameter space of all possible linear combinations of the entries in β.

[2] The test is calculated as

$$\frac{(C\beta)'[C(X'X)^{-1}C']^{-1}(C\beta)}{gS^2} \sim F(n-k),$$

where g is number of independent constraints to be tested (in this case g equals the number of variables deleted, i.e., the number whose parameters have been constrained to zero), n is number of observations, k is number of parameters estimated, S^2 is the square of the standard error of the equation, and C is appropriately defined.

Using risk function (4), an estimator $\hat{\beta}$ is said to be weak mean square error superior (*WMSE*) to an estimator $\tilde{\beta}$ iff $\rho(\hat{\beta}, \beta) \leq \rho(\tilde{\beta}, \beta)$. This implies that $\hat{\beta}$ is closer, on the average, to β in squared Euclidian distance (Wallace, p. 434). Estimator superiority is judged with specific reference to the entries in the β vector. Note that *SMSE* superiority implies *WMSE* superiority, since if $\hat{\beta}$ is *SMSE* superior to $\tilde{\beta}$

$$(6)\quad \rho(\hat{\beta}, \beta) - \rho(\tilde{\beta}, \beta) = tr\, MSE(\hat{\beta}, \beta) - tr\, MSE(\tilde{\beta}, \beta) \leq 0,$$

where tr is the trace operator. That is, under *SMSE* superiority of $\hat{\beta}$ over $\tilde{\beta}$, $MSE(\hat{\beta}, \beta) - MSE(\tilde{\beta}, \beta)$ will be negative semidefinite, and thus the difference between the traces in (6) will be less than or equal to zero, satisfying the *WMSE* criterion. *WMSE* superiority is necessary, but not sufficient, for *SMSE* superiority.

Using the risk function (5), $X\hat{\beta}$ is superior to $X\tilde{\beta}$ in predicting $E(Y|X) = X\beta$ iff $\rho(X\hat{\beta}, X\beta) \leq \rho(X\tilde{\beta}, X\beta)$. This implies that $X\hat{\beta}$ is closer, on the average, to $E(Y|X) = X\beta$ in squared Euclidean distance. Estimator superiority is judged with reference to the specific linear combinations of the entries in the β vector inherent to $X\beta$. Note that *SMSE* superiority also implies superiority in this predictive sense, since if $C'\hat{\beta}$ has mean square error less than or equal to that of $C'\tilde{\beta}$ for all choices of the real vector **C**, C' can be chosen to be the various rows of the matrix X, and the result on predictive superiority follows. Predictive superiority in terms of (5) is necessary, but not sufficient, for *SMSE* superiority.

If the researcher knew the values of (3), (4), or (5) for two different estimators under consideration, and (3), (4), or (5) were deemed to represent adequately the risks of the estimators, then the estimator exhibiting the lower risk value clearly would be chosen. Of course, in practice, the researcher rarely if ever has knowledge of the values of risk measures (3), (4), or (5). The researcher then has two options with which to proceed. One option is to test the hypothesis that the restricted estimator is *SMSE*-superior, *WMSE*-superior, or superior in the predictive sense to the unrestricted model.

Toro-Vizcarrondo and Wallace have shown that the restricted estimator will be *SMSE*-superior to the conventional least squares estimator when the noncentrality parameter, Θ, of the conventional F-test of the restrictions is less than or equal to .5. Bock, Judge, and Yancey have shown that the restricted estimator is superior in the sense of predictive risk function (5) if the noncentrality parameter of the F-test is less than or equal to $J/2$, where J is the number of independent restrictions tested. Bock, Judge, and Yancey also have exhibited the upper bound for the noncentrality parameter, below which the restricted estimator is superior using the risk function (4); however, the bound depends on the structure of the problem under consideration, and thus a general bound cannot be stated.

The null hypothesis of the test is that the noncentrality parameter is less than or equal to the upper bound for superiority associated with the risk measure chosen. The test is accomplished using the standard F-statistic, and the critical value is generated using the noncentral F distribution with noncentrality equal to the relevant upper bound, and type I error chosen by the researcher. The null hypothesis of superiority is rejected or not at the chosen level of type I error depending on whether the calculated F value exceeds the critical value. Thus, the test in this context provides evidence as to whether an estimator is superior to an alternative estimator based on a specific risk measure.

A second option, which is often followed, is to choose between the restricted and unrestricted estimator based on the outcome of a statistical test of the restrictions. The researcher then is thrust into the pretesting dilemma (Wallace). An intuitively appealing approach to model choice would be to test statistically whether the value of the noncentrality parameter of the F-statistic were greater or less than the appropriate critical upper bound associated with the chosen risk measure, and choose the unrestricted or restricted model accordingly. However, the statistical test of the restrictions is subject to errors whose frequencies, given the number of restrictions and degrees of freedom, are governed by the probability of type I error set for the test. That is, in a repeated sampling context, there will be a nonzero probability of choosing the estimator with the higher risk function value when a pretest is used to choose the final model. Therefore, the pretest estimator, as the final estimator is called, will be a probabilistic mixture of the restricted and unrestricted estimators, and will exhibit variance and bias properties different from either the restricted or unrestricted models. However, a general characteristic of the pretest risk functions

[i.e., (4) and (5)] is that their risk values lie above the minimum of the risk values of the restricted and least squares estimators for all values of noncentrality. This underscores the fact that in a repeated sampling context, the researcher utilizing pretesting for final model choice will never be able to attain the minimum risk that would accrue to an estimator chosen on the basis of a known value of noncentrality (i.e., known degree of validity in the restrictions).

Because the level chosen for the probability of type-*I* error will affect the mixture of the restricted and unrestricted estimators (and hence the properties of the pretest estimator), a question arises as to the optimal level of the type-*I* error to use in a pretest. One method used to choose type-*I* errors, and hence critical test values, and the method used in this study, is the minimax regret approach of Brook. The minimax regret approach chooses the level of type-*I* error so as to minimize simultaneously the maximum positive difference (regret) between the risk functions of the pretest estimator and the restricted estimator, and the maximum positive difference (regret) between the risk functions of the pretest and unrestricted estimator over all potential values of the noncentrality parameter Θ. Thus, in effect, the potentially worst additional risk cost that the researcher faces for not knowing the noncentrality parameter associated with the restrictions is minimized by the minimax regret procedure.

The minimax regret procedure has been developed for risk functions (4) and (5). There is currently no procedure corresponding to risk measure (3). It should be noted that the Brook minimax regret procedure utilizes a diffuse prior on the noncentrality parameter, which implies that the researcher is completely ignorant with regard to the validity of the restrictions. Thus, the minimax critical values tend to be rather conservative, because in most applications restrictions are applied with the presupposition that the restrictions are approximately correct—Θ is small (Wallace, p. 438), and a prior on Θ weighting values of Θ close to zero more heavily will tend to increase a weighted minimax regret critical value.

The specific procedure used in this study to assess the relative accuracies of the restricted and unrestricted estimators, and to decide upon a final estimator, was a hybrid of the two concepts discussed above. An *F*-test of the restrictions was constructed. Then the probability of a noncentral *F* being greater than or equal to the calculated *F*-statistic was determined, where the noncentrality parameter was set equal to the *SMSE* bound of .5. The probability value so determined was used as an indicator of confidence in the null hypothesis of *SMSE* superiority of the restricted estimator, and of course is referred to in the statistics literature as the most impressive confidence level of the test. The probability value associated with the test of restricting all three of the government-planning period dummy variable coefficients to zero was determined to be $P[F(3, 19; .5)] \geq 1.78 = .29$. The results lend a fair amount of support to the hypothesis that the restricted estimator (model 2 in table 2) is *SMSE* superior to the least squares estimator (model 1).

Next, the minimax regret critical value associated with the predictive risk measure (5) was calculated following procedures suggested by Brook (tabled values applicable to the case at hand were not available) and was found to be 1.93. Since the calculated *F*-value was $1.78 < 1.93$, the restricted estimator (model 2) is the final model chosen based on minimax regret for the predictive risk measure. The result was interpreted in its literal context—if the researcher were completely ignorant of the validity of the proposed restrictions and wished to minimize the maximum potential positive difference between the values of the pretest estimator's predictive risk measure and the values of the risk measure of the restricted and least squares estimators over all possible values of noncentrality, the choice would be the restricted estimator.

Finally, the minimax regret critical value associated with the weak mean square error risk measure (4) was calculated following Brook (again, the few tabled values reported by Brook were not applicable) and found to be 1.61 in this case. Thus, based on minimax regret, and the weak mean square error risk measure, maximum regret is minimized by choosing the least squares estimator (model 1).

Therefore, the signals were mixed regarding the relative accuracies of the restricted and least squares estimators. We chose to concentrate on the restricted estimator of the production function because, for reasons discussed earlier, our prior notions suggest that the effects of the government planning periods were near zero, and that the noncentrality asso-

ciated with the three zero restrictions should be more heavily weighted for small values.

It should be noted further that the standard critical central F-value for 3 and 19 degrees of freedom, and level of type I error equal to .05, is 3.13. Thus, the null hypothesis that the government-planning period dummy variables have zero coefficients cannot be rejected at the standard .05 level. Notice that the minimax regret critical value is substantially lower than the standard critical value, which is typical.

Examination of the reduced OLS model (model 2, table 2) reveals that although standard errors of the parameter estimates were generally reduced, the parameter estimates associated with the capital and time variables remain relatively imprecise. The estimated production elasticity for labor of 1.3244, although reduced, still seems unreasonably high on theoretical grounds. In response to the unsatisfactory performance of this exactly restricted OLS estimator in the presence of severe multicollinearity, the alternative estimation techniques of mixed estimation and principal components regression were subsequently examined.

Mixed Estimation

Often the researcher has prior notions concerning the signs and general ranges of magnitudes of at least some of the parameters in his or her model. This prior information emanates from previous research, economic theory, the institutions surrounding the system, and/or introspection by the researcher. In fact, researchers are admitting implicitly to possessing prior information whenever a model is estimated and subsequently rejected due to nonconformity with the researcher's expectations regarding signs and general magnitudes of the parameters.

The mixed-estimation technique originated by Theil and Goldberger is a method of combining a pure model (based on sample information only) with prior information in the form of stochastic linear constraints on the parameters of a general linear model. The most important property of the mixed estimator from the standpoint of the multicollinearity problem is that the potential exists for obtaining estimates that are lower in mean square error measure than estimates using (pure) OLS. Hypothesis tests of the mean square error superiority of mixed estimates based on the noncentral F distribution have been developed (Yancey, Judge, Bock; Judge, Yancey, Bock).

One source of information influencing the authors' prior notions concerning Thai agriculture were the results from previous studies of aggregate agricultural productivities in other countries. Table 3 summarizes the studies surveyed.

Reflecting on previous research and on direct observation of the agricultural sector in Thailand, the following estimates of the ranges and general magnitudes of agricultural output elasticities with respect to land, labor, and capital were decided upon by the authors:

$$(7)\quad \begin{aligned} &E_{Q,LAND} \in [.10, .50] \text{ with probability } .95,\\ &E_{Q,LABOR} \in [.25, .85] \text{ with probability } .95,\\ &E_{Q,CAPITAL} \in [0., .30] \text{ with probability } .95.\end{aligned}$$

The prior point estimates of the elasticities were designated as the midpoints of the intervals in (7), and estimates were assumed to be generated from normal priors with variances .01, .0225, and .005625, respectively, and with zero covariances. The stochastic restrictions are represented as

$$(8)\qquad \mathbf{R}\beta + \mathbf{v} = r,$$

where $\mathbf{R}\beta$ is a (3×1) vector representing the land, labor, and capital elasticities, $\mathbf{v}$ is a (3×1) vector of normally distributed disturbances, and $r' = (.3, .55, .15)$.

The production function (1) was estimated subject to the stochastic constraints on the magnitudes of the output elasticities with respect to land, labor, and capital. The results are presented in model 3 of table 2. Judging by the t-values associated with the parameter es-

Table 3. Relative Importance of Land, Labor, and Capital in Agricultural Output of Selected Countries in Selected Time Periods

		Relative Input Weights

Sources: [a] Ho; [b] Akino and Hayami; [c] Tang 1963; [d] Khan; [e] Griliches; [f] Buck; and Tang, n.d.

timates, the coefficients on land, labor, capital, and time appear to have been estimated relatively precisely, while the dummy variable coefficient estimates appear to be much less precise.

In this case, there were two sets of constraints that required examination. The first set of three restrictions, as before, refer to the deletion of the government-planning period dummy variables from the model and are exact linear restrictions. The second set of three constraints refer to the stochastic restrictions on the output elasticities with respect to land, labor, and capital (7) and (8). The alternative estimators of interest here are the mixed estimator with dummy variables deleted (i.e., the restricted model) and the OLS estimator with dummy variables included (the unrestricted model).

In assessing the relative accuracy of the two estimators, a procedure analogous to that used previously was followed. To be specific, the stochastically restricted model was first converted to a generalized equality-restricted estimator following Judge, Yancey, and Bock. Then, as before, an F-statistic was calculated corresponding to the restrictions,[3] which in this case referred to the three exact and three stochastic restrictions, and its value was 1.25 (see Judge, Yancey, and Bock). The probability that a noncentral F-variate with 6 and 19 degrees of freedom and noncentrality equal to .5 is greater than or equal to 1.25 was calculated to be $P[F(6, 19; .5)] \geq 1.25 = .41$. This result provided rather strong support for the hypothesis that the mixed estimator with dummy variables deleted was *SMSE* superior to the ordinary least squares estimator. The minimax regret critical value based on the predictive risk measure was 1.96, and thus the mixed estimator with dummy variables deleted was the choice based on minimax regret for the predictive risk measure. The minimax regret critical value based on the weak mean square error risk measure was 1.22, and thus the least squares estimator was the choice in this last case. It should be noted that the conventional critical central F-value for 6 and 19 degrees of freedom, and level of type I error equal to .05, is 2.63. Thus, the null hypothesis that the government-planning period dummy variables have zero coefficients, and that the sample and stochastic prior information are compatible (Theil) cannot be rejected.

Again, accuracy signals are mixed. We again chose to concentrate on the mixed estimator with dummy variables deleted, because our prior notions suggested that the noncentrality should be more heavily weighted for small values; that is, we felt that the biases in our restrictions, if any, should be low.

For the mixed estimator (model 4, table 2), the share of the posterior precision due to the stochastic prior information (Theil) was calculated to be .48. Therefore, nearly half of the posterior precision of the mixed estimator was due to stochastic prior information, while slightly more than half was due to stochastic sample information.

The mixed estimates (model 4) of the output elasticities with respect to land, labor, and capital were each lower in value than were the corresponding final least square estimates. The most notably different estimates are the estimate of the labor elasticity, which was reduced in magnitude by more than half, and the effect of the time technology proxy, which changed from having a negative to having a positive effect. The estimate of the homogeneity of the production function conditional on time was reduced from 1.9927, estimated via least squares, to 1.0872, estimated via mixed estimation. The coefficients estimated by the mixed model are considered much more reasonable on theoretical grounds than those estimated by the pure OLS or the exact linear restrictions models. Examination of the t-values associated with the mixed coefficient estimates suggest that the precision in estimation has been improved substantially over the least squares approach, mitigating the effects of a rather severe multicollinearity problem.

Principal Components Regression

In the PCR technique, a set of explanatory variables is converted into a set of orthogonal components via an information preserving orthogonal transformation. One or more components are deleted from the analysis by some established criterion (Hill, Fomby, Johnson), and a regression of the dependent variable on the remaining components is performed. Estimates of the parameters associated with the original explanatory variables can be obtained

[3] It should be noted that in the case of mixed estimation, testing results are only asymptotically valid, because the test statistics involve the true variance, σ^2, of the disturbances, μ, in a nontrivial way, for which s^2, a consistent estimate of σ^2, is substituted (see Judge, Yancey, Bock).

by substituting for the components in the regression their equivalent in terms of linear combinations of the explanatory variables (see J. Johnston, pp. 329–30).

The PCR estimates, being restricted estimators, generally will have lower variances than OLS estimates, but they generally will be biased. Under appropriate conditions, the PCR estimator will dominate the OLS estimator in measures of mean square error (Hill, Fomby, Johnson). It is this potential reduction in mean square error that makes the PCR technique attractive for mitigating the effects of multicollinearity.

It was desirable in the PCR analysis to maintain the integrity of the planning-period dummy variables for the hypothesis-testing objectives. Consequently, only a partial PCR procedure was used. Specifically, the natural logarithms of land, labor, and capital, together with the time variable were converted into four orthogonal principal components and a regression of agricultural output on these components and the three dummy variables was performed. The results are displayed in model 6 of table 2.

Upon examining the four principal components ordered according to increasing characteristic roots, it was found that the fourth component accounted for more than 98% of the total variation in the natural logarithms of land, labor, and capital, and in the time variable. Consequently, the deletion of the first three principal components, together with deletion of the planning-period dummy variables from the regression, was contemplated.

The probability of a noncentral F with 6 and 19 degrees of freedom and noncentrality equal to .5 being greater than or equal to 1.27, the calculated F statistic corresponding to the six zero restrictions, was found to be $P(F(6, 19; .5) \geq 1.27) = .40$. This provided significant support for the null hypothesis that the PCR estimator was strong *SMSE* superior to the least squares estimator. The minimax regret critical value for the predictive risk measure was 1.96. Thus, the PCR estimator was the choice based on minimax regret for the predictive risk measure. The minimax regret critical value for the weak mean square error risk measure was 1.45. Thus, the PCR estimator was also the choice based on minimax regret for weak mean square error risk.

In this case, all accuracy measures examined resulted in the PCR estimator being chosen as superior to the least squares estimator. It should again be noted that the null hypothesis of zero coefficients on the dummy variables, as well as zero coefficients on three principal components, cannot be rejected at the standard .05 level of type I error, since the central F critical value for 6 and 19 degrees of freedom equals 2.63.

The final PCR model listed as model 7 in table 2 was one that retained only the principal component with the largest characteristic root, and deleted all other components along with the three planning-period dummy variables. In model 5 of table 2, the fourth principal component was replaced with its equivalent linear combination of $\ln L$, $\ln N$, $\ln K$, and t to derive parameter estimates associated with these variables. The estimates of the land, labor, and capital output elasticities, and especially the coefficient on time observed in model 5, are remarkably similar to those estimated in model 4 via mixed estimation. The principal components estimates in model 5, of course, are based only on sample information. Again, the individual output elasticities and the conditional degree of homogeneity of the production function, equal to 1.0261, appear much more reasonable on theoretical grounds than the estimates generated by models 1 and 2. The estimates using principal components regression appear to be very precise, although it should be noted that due to the retention of only one component, the randomness inherent in the estimates of the land, labor, capital, and time coefficients is one-dimensional. This is reflected by the identical t-values displayed for model 5.

Contribution of Increased Input Use and Technological Progress to Agricultural Output Growth

In order to ascertain the contribution of conventional inputs and neutral technological progess on Thai agricultural output growth, the increase in agricultural output between 1950 and 1976 was decomposed into a movement along the 1950 production surface because of increased use of conventional inputs and an upward shift in the production surface caused by neutral technological progress. Output share estimates and technological progress growth-rate estimates using parameter estimates derived from exactly restricted least squares (model 2), mixed estimation (model 4), and principal components regression (model 5) are displayed in table 4.

Table 4. Shares of Conventional Input Expansion and Technological Progress in Increased Agricultural Output in Thailand, and Growth Rate Due to Technological Advance, 1950–76

Estimating Technique	Input Share	Technology Share	Technology Induced[a] Output Growth Rate
Restricted least squares	1.525	−.525	−.0115 (−.50)
Mixed estimation	.628	.372	.0110 (1.971)
Principal component regression	.624	.376	.0111 (38.853)

[a] The growth rate is given as $(dQ/dt)/Q$, that is, the coefficient of t in the models. The values in parentheses are the t-values associated with the estimated growth rates.

The restricted least squares estimates would indicate that there was technological decay rather than growth. Given the imprecision with which the coefficient on the technology variable was estimated, together with the rather suspect size of the output elasticity with respect to labor, it seems advisable to concentrate on the results provided by mixed estimation and principal component regression. These results are remarkably similar, indicating that the increase in conventional input levels from 1950 to 1976 would account for slightly more than 62% of the agricultural output growth, while technological growth would account for the remainder. Output growth due to neutral technological progress was estimated to be about 1.1% per year by both of these methods.

Summary and Conclusions

The techniques of mixed estimation and of principal components regression (PCR) were each used in an effort to mitigate the effects of a severe multicollinearity problem that was preventing accurate estimation by OLS techniques of an aggregate agricultural production function for Thailand. In addition, pretest considerations of the process of selecting a final specification for each technique utilized were formally addressed.

Both mixed estimation and PCR markedly improved the precision and theoretical reasonableness of estimated parameters on land, labor, capital, and time (a technology proxy). Despite the contrasting conceptual foundations of mixed estimation and PCR, the numerical results were remarkably similar in this application. Both approaches estimated the rate of Thai output growth attributable to neutral technological progress to be about 1.1% per year between 1950 and 1976, whereas a negative rate was estimated by OLS. Both mixed estimation and PCR estimated the degree of homogeneity of the utilized Cobb-Douglas production function to be between 1.0 and 1.1, whereas the comparable OLS estimate was nearly equal to 2.0. The results of mixed estimation and PCR each attributed slightly over one-third of total Thai output growth during 1950–76 to neutral technological progress and the remaining two-thirds to expanded use of land, labor, and capital. None of the estimating techniques employed detected a statistically significant differential impact of economic planning periods on the rate of neutral technological progress in Thai agriculture.

In view of the consistency of these quantitative results, the authors believe the qualitative conclusion that advances in technology played an important role in Thai agriculture during the past three decades cannot be denied. Explanations for this apparent realization of some productivity gains in Thai agriculture, and the apparent neutral impact of the Thai government's economic planning periods, call for a more explicit examination of the Thai agricultural development experience.

While no significant shifts in Thai government agricultural policies (including expenditure rates) were found among the different subplanning periods, the agricultural sector continued to receive a large share of the government's total budget (Tasanasanta, chap. 4; Silcock, p. 186). These Thai government policies and programs may have contributed to the agricultural productivity gains through impacts on crop diversification and improved cultivation practices as well as through some increased provisioning of irrigation water-control facilities. Tasanasanta (chap. 4) shows a significant trend of crop diversification over the period attributed to improved farmer knowledge of nonrice cultivation techniques and seeds, and reinforced by the "rice premium policy" (which artifically lowered the domestic price of rice).

Paralleling crop diversification trends, imports of chemical fertilizers, pesticides and

fungicides increased rather significantly until the mid-1960s, but have increased at much lower rates since then (Tasanasanta). Domestic production of chemical fertilizers and pesticides has been minimal.

Government policies also have helped to improve irrigation, transportation, and extension education in agriculture since 1950. In aggregate terms, there were only 3.8 million irrigated rais in 1947, about 9.8 million rais (or about 14% of total cultivated land) in 1964–66, and 14 million rais (20% of total cultivated land) in 1969 (Tasanasanta, p. 86). Between 1950 and 1976, considerable road construction and railway rehabilitation had been undertaken, while substantial agricultural extension-education programs have been promoted by the government over the same period—including agricultural research at experiment stations throughout the country.

Nevertheless, the quantity and distribution of government infrastructure investment continue to be important factors limiting the acceleration of productivity growth in Thai agriculture. The Thai irrigation system still is far below its potential insofar as the irrigated area accounts for only one-fifth of the cultivated area, and 80% of these irrigated areas are located in the central region. Feeder canals, dikes, and other water distribution facilities have not kept pace with dam construction. The northeast region, where water is scarce, has been waiting for an effective irrigation system. Roadways show a similar pattern with irrigation developments; many connecting roads have not been constructed to permit interregional traffic which would bring large numbers of people into contact with external markets.

Notwithstanding the possible limitations on these interpretative explanations, this paper has demonstrated the potential usefulness of exact and stochastic restrictions in increasing precision of estimated parameters in the presence of extreme multicollinearity. It also formally addressed pretest considerations of the estimators which emerged from the model selection process. The precise estimation of this particular aggregate agricultural production function, and the subsequent analysis of agricultural output growth in Thailand, would not have been feasible had the alternatives to the OLS-estimating technique not been available.

Notes

Benefits, Costs, and Distributional Consequences of a Publicly Assisted Marketing Cooperative

John Hoehn, Lynn W. Robbins, and Kurt R. Anschel

During the last two decades, public policy makers have recognized a need to enhance the earning capacity of low income rural residents. For the rural population now supplementing minimal incomes with income from agricultural production, current policy instruments are slow in effect. Designed primarily for long-run development of nonagricultural employment through industrialization and the enhancement of human capital through schooling, such policies largely ignore small farms as a transitional source of income and employment. An exception to this general tendency, Title III of the Economic Opportunity Act of 1964 planned to strengthen the income earning capacity of small farm households.

Although larger farms have been served by organizing cooperatively, small, low income farms have appeared limited in their ability to organize cooperatively by inadequate investment capital. Title III sought to ease this perceived capital constraint with a program of grants and loans. The primary objectives were (*a*) to provide the opportunity for increased farm income through productive employment and (*b*) to direct this income enhancement opportunity toward otherwise low income households (U.S. Congress). Existing evaluations tend to stress more the need for changes in administrative procedures than careful consideration of project benefits and costs. Where income changes have been estimated, analytic methods are unclear and leave the significance and validity of such results in doubt. The role of Title III in enhancing the earning capacity of low income rural households has yet to be measured and analyzed. This paper presents a case study that does define Title III's role in affecting rural incomes.

Research Design

The benefits or injury which cooperative organization may offer a community of low income farm households is evaluated through a case study of a southeastern Kentucky marketing cooperative. To parallel the objectives of Title III, the study attempts (*a*) to estimate the magnitude of income benefits accruing to the members and to society as a result of public investment in the cooperative and (*b*) to determine resulting income distributional consequences among cooperative members.

The study cooperative was organized in 1969 and funded without member equity through a Farmers' Home Administration (FmHA) loan and an Office of Economic Opportunity grant. To ensure adequate operating capital, grant disbursal was planned over an eleven-year period. With grant disbursements diminishing each year, member dues and marketing charges progressively assume a larger share of operating capital. The cooperative has yet to generate savings. Assembly and marketing services are performed for a membership that has varied from 300 to 500 producers. Tomatoes, cabbage, and green peppers are sold to fresh markets while growers also may contract for sales of red peppers to processing markets. Cooperative sales have ranged from \$416,000 to \$572,000 in recent years.

Because the output of the cooperative represents only a small increment in market supply, no measurable net change in consumer benefits can be expected. Any change in private or social benefits accrues to those engaged in the production of crops or to those seasonally employed in cooperative processing. The concept of benefits is based on the notion of opportunity cost. Opportunity cost consists of the income attainable had equivalent resources been employed in the next best alternative. Member benefits may be represented as

$$MB_{ik} = \sum_j (R_{ijk} - U_{ijk} - OC_{ijk}),$$

Where MB_{ik} is net benefit received by kth member in ith year; R_{ijk}, the revenue received by kth member in the ith year through sale to the cooperative of output from the jth vegetable enterprise; U_{ijk}, the cash production costs for the ith year and jth enterprise; and OC_{ijk}, the opportunity costs due to income foregone in the ith year by not employing resources of the jth crop in the next best income-producing alternative. Net social benefits derived from the production of the kth member's crop, PB_{ik}, are member benefits plus the wage bill paid to hired labor, less the opportunity costs of hired labor. For labor seasonally employed in the processing and packing of cooperative output, a similar model may be constructed where LB_{il} is the net benefit to the lth worker in the ith year, R_{il} is the

Portions of the work reported in this paper were funded by the Cooperatives Division of the U.S. Department of Agriculture.

income received in wages and OC_{it} is the income foregone in the next best alternative employment opportunity.

Social costs incurred through public investment in the cooperative arise over time from both grants and loans. While the full dollar value of the grant is a relevant social cost, the social cost of the loan is the difference between annual repayments made on the loan at the lending rate of interest and the return foregone had the loan been otherwise invested. For a given year, public sector costs are calculated as

$$C_i = G_i + (Ap_i - Ar_i),$$

where C_i is public sector costs in the ith year; G_i, the grants made to the cooperative in the ith year; Ap_i, the foregone annual repayment in the ith year had the loan principal been invested at some discount rate p; and Ar_i, the annual repayment in the ith year on loan principal at the 4⅛% interest rate established by FmHA.

The above measures of benefits and costs lead to a comparison of the real social gain or loss brought about by investment relative to the cost of investment. As a ratio of benefits to investment costs, the analysis discloses the average efficiency of investment. The model is

$$\frac{B}{C} = \frac{\sum_i (1 + p)^{-i} \left[\sum_k PB_{ik} + \sum_t LB_{it} \right]}{\sum (1 + p)^{-i} C_i},$$

where B is present value of project benefits; C, the present value of project investment costs; and p, the socially relevant discount rate. The time horizon, i, can be established by reference to the repayment schedule of the cooperative's FmHA loan. The thirty-year mortgage implies that public sector costs were anticipated over a thirty-year period beginning in January 1969. The value of i, therefore, ranges over the integer values from zero to thirty.[1] Because both benefits and costs occur over time, a discount rate is necessary to ensure that benefits and costs are commensurable. Two discount rates are enlisted in this study. The first calculation is at 5% to reflect the average return on U.S. Treasury securities in the late 1960s, the period when investment in the cooperative was initiated. A second calculation is at 10% and corresponds to the Office of Management and Budget discount rate of the 1970s (Sassone and Schaffer).

Estimating Benefits

Three data sources were critical to the analysis. First, annual grower-contract summaries kept by the cooperative identified individual growers, listed acreages planned by members, and detailed the sales revenues of each grower. Second, to estimate production costs, opportunity costs, and household income, a sample of 160 cooperative members was randomly selected from among 433 participants who had indicated a willingness to produce a crop in 1977. Of the 160 members sampled, 137 respondents completed usable interview schedules. The survey schedule detailed members' experiences with the cooperative and with vegetable crops, the growers' tenure with respect to the acreage planted, household composition, off-farm employment and income, production practices and output from crop and livestock enterprises, and, finally, the growers' income earning alternatives to the production of crops for sale to the cooperative. When respondents were unable to identify an income-producing alternative, opportunity costs were later priced at zero. Third, the revenue and cost-budgeting process was completed by reference to standard budgets (Allen et al.). Data from these budgets became important where collection through the survey would have been impractical.[2]

Social and member benefits derived from production are estimated by combining the cross-sectional results of the survey with the yearly revenue and planned acreage data available from cooperatives records for each member. Considering costs as a function of planned acreage, social benefits from production for 1971 through 1978 are estimated as

$$PB_i = \sum_j \sum_k R_{ijk} - \sum_j \left[\frac{\sum_r C_{rj}}{a + \sum_r A_{rj}} \left(\sum_k AP_{ijk} \right) \right],$$

where PB_i is total benefits from crop production in the ith year; R_{ijk}, revenue received by the kth producer in the ith year for sale of the jth crop; A_{rj}, acreage planned by rth respondent in production of the jth crop in 1977; AP_{ijk}, acreage planned by the kth member for production of jth crop in the ith year; C_{rj}, production costs, including relevant opportunity costs, for the jth vegetable crop grown by the rth respondent; a, sum of acreage planned by those in sample who did not actually grow a crop in 1977; and i, 3, . . . , 10 and corresponds to the years 1971 to 1978. To reflect the difference in private member benefits, MB_{ik}, and social benefits, PB_{ik}, derived from production, C_{rj}, is adjusted. Where private benefits to member households are of concern, C_{rj} includes the full wage bill of any hired labor. When estimating social benefits, C_{rj} includes only the opportunity cost of hired labor. Where hired labor was employed throughout the production season, opportunity costs for hired labor are

[1] To adjust nominal values for changes in the purchasing power of the dollar, all terms are transformed to 1977 constant dollar values by use of the consumer price index. The same adjustment procedure will be used throughout this study where nominal values originate in different time periods.

[2] For example, detailing overhead and machinery costs for each respondent would have carried interviews beyond the practical limit of thirty to forty minutes. Even without some practical limit to interview length, different respondent accounting methods for such costs might well have led to incommensurable results.

valued at the respondent's average per hour opportunity wage. If hired labor was employed only briefly, at harvest, for example, it is assumed that hired labor otherwise would be unemployed and therefore is valued at zero opportunity cost.

For 1969 and 1970, no data are available from the cooperative regarding acreage planned or revenue received by the members. Lacking a more adequate procedure, benefits derived by the membership in 1969 and 1970 are assumed to be equal to their 1971 level.

Benefit-cost analysis commonly requires that a benefit stream be projected into the future. As the time horizon increases, so too does uncertainty regarding the projected benefit stream. Two factors influencing future member benefits are technological innovation and changes in the members' income earning alternatives. Neither of these factors is subject to rigorous probabilistic definition.

In this study, the future benefit stream derived from the services of the cooperative is projected on the basis of the past. Annual future benefits are based upon average annual benefits achieved by the total membership in the period from 1971 to 1978. Average annual benefits are estimated because no discernible trends exist for either sales, membership, or sales per member. Total cooperative sales increased through 1974, declined until 1977 and then increased slightly in 1978. Membership increased through 1974 and since has declined somewhat each year. Gross revenues per member increased through 1974, declined through 1976, and increased in 1977 and 1978.

To account for the uncertainty regarding the permanence of the production-benefit stream, benefit-cost ratios are separately computed under two different assumptions. First, benefits from production are assumed to remain constant and equal to the annual average benefits achieved from 1971 to 1978. Second, the future benefit stream from production is assumed to decline from 1979 onward at a rate of 7% per year. This second assumption is intended to account for (*a*) the possibility of generally rising opportunity costs to labor and concomitant decline in the stock of involuntarily unemployed labor, and (*b*) the possible effects of technological innovation. The choice of a 7% rate is somewhat arbitrary but implies that benefits, measured in constant 1977 dollars, will be approximately halved over each ten-year period.

For labor seasonally employed in the processing and packing of cooperative output, no sampling data is available to estimate alternative employment opportunities. Without adequate sampling data, a portion of the wage bill paid to these temporary workers is included in the benefit-cost analysis under two different assumptions. First, opportunity costs for these workers are assumed to equal zero in the cooperative's first year and to increase on a straight line basis to 80% of the wage bill in the thirtieth year. Wages paid in years eleven to thirty equal the average wage bill of the cooperative in the years 1969 to 1978. Second, to test the sensitivity of the benefit-cost results to the inclusion of seasonal employment benefits, additional ratios are calculated with opportunity costs equal to 100% of the wage bill in all years. This second assumption excludes entirely the possibility of incremental benefits accruing to those seasonally employed at the cooperative.

Benefit-Cost Results

Present value estimates for both benefit and cost streams permit a comparison of the net social gain brought about by public investment in the cooperative relative to the social costs. Depending upon the assumptions adopted and the discount rate selected, socially relevant present values for benefit streams range from $329,017 to $826,092 (table 1).

Given the certainty of public investment by both size and type, social costs vary only with the discount rate and range from $660,979 under the 10% rate to $686,866 under the 5% discount rate (table

Table 1. Present Values of Benefit Streams in Year "0" by Assumption and Discount Rate

	Total Benefit Streams by:			
Discount Rate	Assumptions 1 and 3	Assumptions 1 and 4	Assumptions 2 and 3	Assumptions 2 and 4
	$			
5%	826,292.45	635,305.94	693,922.19	503,135.68
	(591,593.19)[a]	(591,593.19)	(309,783.61)	(309,783.61)
10%	464.044.25	377,407.76	415,653.10	329.016.61
	(233,341.27)	(233,341.27)	(203,388.55)	(203,385.55)

Assumption 1: Benefits from crop production remain constant from 1979 onward at 1971 to 1978 average.
Assumption 2: Benefits from crop production decline at 7% per year from their 1971 to 1978 average beginning in 1979.
Assumption 3: Opportunity costs for seasonally employed rise from zero to 80% of the wage bill over the thirty-year period.
Assumption 4: Opportunity costs for seasonally employed equal 100% of the wage bill in all years.

[a] Parentheses indicate private benefits to members.

Table 2. Present Values of Public Sector Project Costs at Stated Discount Rates

Source of Cost	Present Values in Year t_0 at Discount Rate 5%	10%
	-------- $	--------
Interest subsidy[a]	17,016.41	107,672.97
Grant monies[b]	669,849.58	553,305.95
Total public sector cost	686,865.99	660,978.92

[a] The accounting model is $\sum_t (Ap_t - Ar_t)/(1 + p)^t$.

[b] The accounting model is $\sum_t G_t/(1 + p)^t$.

2). Examining the social cost components, the 10% rate weights more heavily the cost of subsidized interest rate while the 5% rate places more emphasis on the cost of the grants made to the cooperative.

Estimated benefit-cost ratios relevant to public investment range from 0.50 to 1.20, depending upon the assumptions adopted and the discount rate selected (table 3). The ratios imply that, on the average, the return from diverting funds to the cooperative ranges from $0.50 to $1.20 for every dollar invested.

A weakness inherent in benefit-cost analysis results from uncertainty in projecting benefit streams. To deal with uncertainty in benefit projection the four assumptions discussed previously were utilized. Of the assumptions, the second and third assumptions appear to provide the most reasonable projection of benefits and thus result in more reliable benefit-cost ratios. Greatest uncertainty stems from estimating benefits to seasonally employed labor. Over the thirty-year period, these benefits could range from zero to the total value of the

Table 3. Estimated Benefit-Cost Ratios under Differing Assumptions and Discount Rates

	Assumption 1 Discount Rate		Assumption 2 Discount Rate	
	5%	10%	5%	10%
Assumption 3	1.203	0.775	1.010	0.702
Assumption 4	0.925	0.571	0.733	0.498
Private benefits to membership	0.570	0.353	0.451	0.308

Assumption 1: Benefits from crop production constant from 1979 onward at 1971 to 1978 average.
Assumption 2: Benefits from crop production decline at 7% per year from 1971 to 1978 average beginning in 1979.
Assumption 3: Opportunity costs for seasonally employed rise from zero to 80% of the wage bill over the thirty-year period.
Assumption 4: Opportunity costs for seasonally employed equal 100% of wage bill in all years.

wages paid to employees. The assumption that opportunity costs for seasonally employed labor would increase from zero to 80% of the wage bill over the thirty-year period was analyzed as a compromise estimate for this uncertain benefit stream. Again the assumption that opportunity costs for seasonally employed labor would equal 100% of the wage bill in all years was included to weigh the sensitivity of the overall benefit stream to this benefit component.

The direction of change for benefits derived from crop production is more certain. Opportunity costs are likely to increase and thus reduce future benefits from production. Opportunity costs will tend to rise as alternative employment opportunities develop and as local labor gains the skills and knowledge necessary for employment in nonagricultural alternatives. Given these observations, the preferred assumption is that benefits derived from production are approximately halved every ten years after 1978. Employing the two preferred assumptions, the benefit cost ratio is 1.01 at the 5% discount rate and 0.70 at the 10% discount rate.

The desirability of public investment in the cooperative depends upon the discount rate selected, a decision maker's assumptions, and an investment decision criterion. If discount rates properly reflect the investment opportunity costs and if the income distributional objectives may be accomplished through a tax transfer system, the decision not to invest would appear appropriate when the benefit-cost ratio is less than one. With this criterion and a discount rate of 10%, society would be better off by not investing in the cooperative as all benefit-cost ratios are less than one. However, the 5% rate was suggested as the relevant discount rate of the 1960s, the period when investment decisions were actually made. Discounting at 5% and allowing for social benefits to the seasonally employed, estimated benefit-cost ratios indicate the possibility of a small social gain from the cooperative.

Member benefits derived from production are shown in relation to public costs of investment to test for the likelihood of investment in the cooperative by the membership alone. Assuming private investment would occur on the same scale as public investment, the autonomous initiation of the cooperative appears unlikely. Under each assumption and both discount rates, investment cost is at least 43% greater than estimated private benefits.

Income Distributional Effects

A primary objective of public investment in cooperatives is enhanced income-earning opportunities for low income members. The benefit-cost analysis measures allocative efficiency but does not address distributional effectiveness. Where public investment projects have primarily distributional objectives, Weisbrod suggests the concept of target efficiency.

The target efficiency criterion is applied in two directions. The first direction, vertical, addresses the project's ability to apportion benefits toward the intended beneficiary group. This vertical measure discloses (*a*) whether an intended group benefits, and (*b*), if this group does indeed benefit, the proportion of project benefits shared by the group. Vertical efficiency may be measured by the proportion of project benefits shared by the intended beneficiaries. The second direction of target efficiency, horizontal, evaluates the adequacy of benefits received by individuals of the intended beneficiary group (Weisbrod). In practice, horizontal efficiency may be measured by comparing the benefits received by the intended beneficiaries relative to a benefit share considered adequate according to an income standard (Infanger).

To apply the concept of target efficiency in the present analysis, four points must be clarified. First, the intended beneficiaries must be identified. Second, a measure of income must be defined. Third, a minimum income standard must be chosen. Fourth, income levels in the absence of ("without") the cooperative's services need be computed.

The intended beneficiaries of cooperative services are clearly those members who, without the opportunity presented by the cooperative, would be classified as low-income (National Archives, p. 524). By reference to Bureau of the Census guidelines both a measure of income and a standard of income adequacy may be defined. The Bureau of the Census defines income as yearly household receipts from either farm or nonfarm employment less business and farm expenses plus public assistance money payments before deductions for federal and state income taxes (U.S. Bureau of the Census, pp. 193–94). Based on the survey data, income "with" and "without" the services of the cooperative is computed for 1977. The "with" measure of income combines income from all sources, including net income derived from sales to the cooperative. The "without" measure excludes income derived from sales to the cooperative and includes income attainable from the foregone earning activity. To arrive at the relative adequacy of household income both "with" and "without" the services of the cooperative, the standard employed is the matrix of poverty threshold levels published yearly by the Census Bureau. This federal standard adjusts minimum household income requirements for variation in the age and sex of the head of the household, for the number of persons in the household, and for changes in the Consumer Price Index (Bureau of the Census, pp. 195–204).

Vertical Income Distribution

By ranking respondents on "without" income alone and partitioning the resulting "without" income array into quintiles, the vertical efficiency measure is achieved. In table 4, respondent households are grouped into quintiles by their "without" income. All quintiles experience some cash income gain as a result of sales to the cooperative. While the middle income quintiles (2nd, 3rd, and 4th) share in only 19.58% of the cash income gain, the share of the lowest and highest income quintiles (1st and 5th) totals 80.42%. Shares of opportunity costs appear to be almost the inverse of shares of cash income gains. When opportunity costs are subtracted from the cash income gain, the results are striking. The middle income quintiles not only experience a relative decline in income shares, but also incur real income losses. If income maximization is their goal, middle income quintiles would appear to be better off by not participating in the cooperative. While the highest income quintile achieves a gain equal to 76.73% of total respondent benefits, the benefit share of the lowest income quintile is 272.73%.

The effect of these benefit shares on respondent incomes is shown in table 5 where respondents are ranked and arrayed in quintiles by income "without" the cooperative. Results show that there is a slight tendency for total income shares to shift toward lower income quintiles. Perhaps most noticeable is the small effect of benefits, positive or negative, on the total incomes of the four upper quintiles. The second quintile sustains the greatest loss at −2.03% while the fifth quintile experiences a gain

Table 4. Distribution of Benefit Components among Respondents by Income Quintile

		Percentage of Total Benefit Component by Income Quintile[a]				
Benefit Component	Respondent	1st	2nd	3rd	4th	5th
	--- $ ---					
Income derived from crop production for the cooperative[b]	37,164.55	53.45	3.60	12.33	3.65	26.97
Opportunity costs incurred	31,453.65	13.64	18.13	25.41	24.90	17.92
Benefits received	5,710.90	272.73	−76.41	−59.72	−113.33	76.73

Note: Household income measures include allowance for changes in monetary public assistance and transfer payments.
[a] Quintile based upon "without" situation respondent income.
[b] Income derived from crop production is revenue minus cash and overhead costs.

Table 5. Changes in Respondent Income Shares within Quintiles Ranked by "without" Cooperative Generated Household Income[a]

	Quintiles Based on Ranking by "without" Situation Household Income				
	$				
	0–5,372	5,372–8,886	8,886–13,391	13,391–19,385	19,385–42,200
Under "without" situation mean quintile income ($)	3,170.38	7,312.19	10,869.46	15,879.13	25,410.27
Under "with" situation mean quintile income ($)	3,744.49	7,163.65	10,747.65	15,639.41	25,566.79
Percentage change in mean and total quintile income (%)	18.11	−2.03	−1.12	−1.51	0.62

[a] Household income measures include allowance for change in monetary public assistance and transfer payments.

of less than 1%. For the lowest income quintile, benefits derived from the services of the cooperative lead to a substantial increase in quintile income; quintile income increases 18.11% from the "without" situation to the "with."

Horizontal Income Distribution

Horizontal target efficiency measures the adequacy of income increases achieved by low income participants when compared to an income standard. For the households whose incomes fall below the relevant Census Bureau poverty threshold, the household income deficit represents the additional income required to equalize household income with the poverty threshold.[3] The total income deficit is simply the arithmetic sum of individual household income deficits. Because poverty levels remain a relative concept, total income deficits also are estimated for multiples of the relevant poverty thresholds. For a multiple of the poverty threshold, say 0.75, the household income deficit represents the additional income required to equalize household income with 0.75 of the relevant poverty threshold.

[3] This concept is commonly employed by the U.S. Bureau of the Census. See Bureau of the Census.

Results are presented in table 6 and allow a comparison of total income deficits under respective "with" and "without" situations. Total income deficits show a consistent decline across all poverty threshold classes. While tending to diminish in significance as poverty levels rise, the deficit change is greatest for those whose incomes fall below 100% of the poverty level.

Conclusions and Implications

Sizable benefits accrue to low income participants due to services provided by the cooperative. Reducing the net benefit sum, however, are losses experienced by middle income participants. As a whole, benefits accruing to the membership provide insufficient incentive for cooperative formation through private investment alone. Thus, without public investment, social benefits and benefits to the low income members may be lost. In the case of the study cooperative, social benefits do appear to have justified the social costs of public investment at the time investment decisions were made. However, the current 10% Office of Management and Budget discount rate leaves the desirability of simi-

Table 6. Income Deficits of Low Income Respondent Households

Poverty Ratio Classes[a] (Inclusive)	Income Deficit Total "without"	Income Deficit Total "with"	Percentage Change in Income Deficit[b] from "with" to "without"
0.0–0.75	25,396.96	23,031.56	− 9.3
0.0–1.00	53,779.46	48,176.61	−10.4
0.0–1.25	92,623.32	84,661.65	− 8.6
0.0–1.50	146,611.75	136,585.19	− 6.8

Note: Income includes allowance for changes in monetary public assistance and transfer payments.

[a] Poverty ratio is respondent household income divided by the federal poverty threshold relevant to the characteristics of the household in question. See Congressional Budget Office, 1977.

[b] Total income deficit is the additional income required to bring all respondents within the poverty ratio class to the upper bound of the poverty ratio class.

lar present day investment in doubt.[4] Despite these somewhat contrary findings, important conclusions result regarding cooperative organization as a means of enhancing low rural incomes.

First, benefit streams depend on cash income derived from either employment or production and opportunity costs. Though apparent on theoretical grounds, this assertion often is overlooked in project planning and analysis. Because opportunity costs vary between individuals, neither a global endorsement nor a global rejection of low income cooperatives is reasonable. The ability to determine probable benefits and beneficiaries a priori is essential if a goal of public investment for low income cooperatives is social benefits at least equal to social costs. To estimate member benefit levels, prior analysis need consider prospective cash income gains and participant employment alternatives. Both social and private benefits will be greatest, *ceteris paribus*, where low opportunity costs to labor permit labor intensive crop production.

Second, the present analysis has been unable to explore fully the cost side of the benefit-cost ratio. Only actual investment has been considered. With the study cooperative, both public investment and project size appear to have been determined more by agency compromise than a careful consideration of the sales and grower-processing requirements. If both investment and project size had received more adequate planning, benefit-cost ratios likely would be more favorable. The critical question is, "What is the least-cost combination of cooperative services for a given level of benefits?" With this question answered, a combination of loans and grants may be determined which will minimize social costs without unnecessarily jeopardizing the cooperative's financial stability.

[*Received June 1979; revision accepted November 1979.*]

[4] Some may challenge the 10% discount rate as too high. For instance, recent estimates by Boskin result in a discount rate range from 5.6% to 8.9%. However, general policy conclusions are not dependent upon resolving whether the benefit-cost ratio for this particular project is slightly greater or slightly less than one.

An Evaluation of Cooperative Extension Small Farm Programs in the Southern United States

David Orden and Steven T. Buccola

During the past decade, new cooperative extension service programs have been developed for the purpose of aiding small and limited resource farmers. Programs have been implemented primarily in the South, a region in which the 1890 land grant institutions focus attention on disadvantaged minorities and in which small farms remain relatively concentrated. Long-term program goals are to expand educational assistance to individuals not reached by other extension programs, to raise small farm productivity, to increase farm sales revenues, and to improve family living standards. Farmers generally participate for a period of two to four years.

Early pilot programs in Texas (1968) and Missouri (1971) involved the experimental use of paraprofessional field staff, themselves selected small farm operators, who worked with their peers on a one-to-one or "neighbor-to-neighbor" basis (Strickland and Soliman; Wiggins). In 1968, the Alabama Cooperative Extension Service directed its professional agricultural agents to allocate part of their time to similar small farm activities (Maddox, Jones, McDaniel). The success of these efforts reinforced the concepts of developing some extension programs specifically for small farm operators, and of employing paraprofessionals to perform such work. Additional federal funds became available in the mid-1970s and programs were initiated in other states. By 1978, small farm programs in the southern region employed more than 250 full-time field workers, primarily paraprofessionals. Annual program expenditures exceeded $2.2 million.

David Orden is a graduate research assistant in the Department of Agricultural and Applied Economics at the University of Minnesota, and Steven T. Buccola is an assistant professor of agricultural economics at Virginia Polytechnic Institute and State University.

This research project, entitled "An Inventory and Evaluation of Cooperative Extension Programs in the South Aimed at Small and Part-Time Farmers," was funded by the Science and Education Administration, U.S. Department of Agriculture. States included in the study are Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, Missouri, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, and Virginia.

The authors wish to express thanks to Robert Jensen and Dennis Smith for their early guidance in this project, to Charles Beer of the Science and Education Administration for his advice and encouragement, and to extension administrators and small farm program leaders in each state contacted.

Research Objectives

This paper presents partial results of an inventory and evaluation of cooperative extension service programs directed at small farm operators in the southern United States (Orden, Buccola, Edwards). Although several states had summarized or assessed their own small farm efforts prior to this study, no comprehensive regional inventory of resources, or evaluation of program strategies or effectiveness, had been undertaken (Atkinson; Enlow, George, Holik, Wiggins; McAfee; Strickland and Soliman; West, Harrold, Schneeberger, Williamson). Similarly, while several recent studies have examined opportunities for increasing incomes derived from small farms, these studies have provided no evidence that extension assistance programs can induce such increases. For example, Stewart, Hall, and Smith, comparing realized with potential incomes on limited resource farms in eastern Kentucky, concluded (p. 81) that "the potential for increasing income exists," but that "the possibility of achieving this potential needs to be explored in greater depth."

In this light, two purposes of the present study were to identify and describe southern cooperative extension small farm programs, and to evaluate the impact of selected program and nonprogram characteristics on achievement of a crucial program goal: increases in farm sales revenue. Findings provide information relevant to defining program audiences and objectives, estimating expected program outcomes, identifying characteristics of effective programs, and determining the extent to which further commitment of resources to small farm programs appears justified.

Data Sources and Initial Inventory

Twenty-three programs in which field staff provide intensive assistance to individual small farm operators were included in the study. Data were provided by personal interviews with forty-three administrators and state specialists at both 1862 and 1890 land-grant institutions and by survey questionnaires completed by local program supervisors and field staff. One hundred-eighty-seven field workers (thirty-five professional agents and

152 paraprofessionals) and 113 of their local supervisors furnished information concerning their own background, training and activities, and perceptions of program operation. Because the programs studied are based on the principle of one-to-one contact, field staff also were able to draw on their records, progress reports, and personal familiarity with each participant to provide data on the characteristics, resources, participation levels, and sales revenue improvements attained by more than 4,500 farmers participating in small farm programs. This sample represented 76% of the farmers assisted on an intensive basis by field worker respondents. Data were subsequently tabulated so that responses for each farmer were linked to responses of the appropriate field worker, local supervisor, and state program leaders.

Most extension administrators and program leaders indicated that their small farm programs were oriented toward farmers with resources and incomes lower than those of farmers served by other extension programs. Our inventory confirmed that small farm program participants typically do have low incomes, limited farm resources, and moderate educational levels. To illustrate, off-farm income amounted to less than $5,000 for 62% of the participants, yet 70% of the participants were estimated to gross less than $5,000 annually in farm sales. Farm size averaged 108 acres. Approximately 37% of the participants had completed less than eight years of schooling. Three-fourths of the participants had ten or more years of farm experience, but less than one-third had received extension assistance prior to their involvement in a small farm program. Some 59% of the participants were black, partly reflecting the greater incidence of low incomes among minority as opposed to white small farm operators and, partly, the emphasis placed on small farm programs by 1890 land-grant institutions.

The types of individual assistance received by small farm program participants are summarized in table 1. While most small farm programs emphasized similar long-term goals, cited previously, they often differed with respect to short-term objectives. For example, some concentrated on upgrading production practices, others emphasized market development, and still others focused on improvement in home gardening. State programs, and often localities within a program, also varied widely in formal and informal administrative processes, commitment of professional staff and financial resources, and characteristics of field staff.

Table 1. Types of Individual Assistance Received by Participants during the Period of Their Association with a Small Farm Program, Southern Region of the United States, 1977

Program Objective/Type of Assistance[a]	Percentage of Participants[b]
Improve gardening and other food production for home use	42.6
Improve production practices:	
soil testing	67.7
crop production	47.7
livestock production	43.5
Improve enterprise management:	
develop farm records	28.7
develop farm plans	24.3
increase enterprise size	13.8
eliminate enterprises	13.5
add new enterprises	12.6
Increase participation in government programs:	
nonextension agricultural programs	27.9
extension programs	21.4
social programs	5.5
Improve facilities:	
family housing	18.5
farm buildings	16.1
Improve marketing:	
increase quality of product outputs	28.9
expand available markets	17.3

[a] Most farmer-participants received more than one type of assistance.
[b] Indicates assistance at least once during the period of a farmer's association with a small farm program. No distinctions were made as to the intensity or duration of the assistance provided.

Method of Analysis

Analysis of program effectiveness was complicated by the diversity of short-term objectives enunciated by state and local personnel, by the wide range of program characteristics that could affect success measures, and by the equally large number of factors extraneous to the programs that could also influence outcomes (Weiss; Wholey et al.). Our analysis focused on field staff estimates of changes in participants' farm sales revenue during the period of their association with a small farm program. Although this measure is directly related to many long-term program goals, it is not the only indicator of program success. Other activities, for example improving home gardening, are not necessarily reflected in farm sales increases.

To overcome some of the difficulties inherent in comparing the outcomes of diverse program efforts, a conceptual model was developed to explain the degrees of improvement in farm sales revenue experienced by small farm program participants. Changes in farm sales revenue may be responsive to such nonprogram factors as output prices, environmental effects on per acre or per animal yields, and farmer resource bases. Reve-

nue changes also were hypothesized to be sensitive to the level and intensity of a farmer's small farm program participation, either as a result of technical assistance provided by field staff or through an induced change in the farmer's resources. Levels of program participation in turn may be influenced both by farmer receptivity to assistance and by the availability and attractiveness of program activities. The latter two factors are largely controlled by the ability of supervisory and field staff and by program design and fiscal resources, each of which is partly dependent upon federal and state administrative decisions and commitments.

To test these hypotheses and to estimate the effects of various factors on small farm program outcomes, it would have been desirable to employ the available cross-sectional data by regressing farmers' sales volume changes against all the measured factors hypothesized to determine the changes. This approach would minimize specification bias resulting from exclusion of relevant variables. On the other hand, the large quantity of factors thought to affect the sales revenue increases attained by participants implies that such a strategy would result in extensive collinearity among regressors, and hence unduly wide standard errors for some or all coefficient estimates (Kmenta, pp. 338–39).

As an alternative, two approaches were followed. In the first approach, sales volume determinants were divided into blocks of variables and observed changes in participants' sales volume were regressed against each of these blocks separately. The blocks utilized were (*a*) the farmer's physical and human resources at the time he joins a program, (*b*) the levels and types of his participation in an extension small farm program, (*c*) the characteristics of local program staff, and (*d*) local and statewide program characteristics. Measures of output price and environmentally affected yield changes were retained in each equation. In the second approach, factors having especially important implications for program implementation or policy formulation were selected from each block and combined in a single, unified regression model. This approach allowed the effect of each selected factor to be measured in the presence of variables from other blocks.[1]

Results

A summary of the results of the second approach is shown in table 2, where variables are grouped according to the blocks discussed above. The mean value of the dependent variable ($1,169) is consistent with expectations of program supervisory and field staff that many participants would improve farm sales revenue, but that the increases would be modest in most cases. The initial "control" block is a set of zero-one variables that reflect whether output price changes or adverse weather conditions were considered by field staff to have been an important factor affecting participants' sales volume changes. Thus the control variables qualitatively account for the impacts of these external factors on program outcomes.

The second group of variables in table 2, comprising participants' initial farm sales and off-farm income, represents the farm resources block. Increases in participants' farm sales revenue were, on average, greater among farms with relatively high initial sales levels and among farmers with relatively high off-farm incomes. In our earlier analysis, when only farm resource variables were included in the regression model (not shown here), sales increases were also greater for younger farmers and for those with relatively more education. Thus, participants' sales improvements are partially determined by their resource characteristics, implying attributes of the selected target audience should be considered in setting realistic program goals.

In the third or program participation block of table 2, two sets of zero-one variables are used to reflect the nature of a farmer's involvement in a small farm program. The first set identifies whether a farmer attended meetings only, events only, or a combination of both. Results indicate that farmers who participated only in educational meetings did not experience greater sales revenue increases than a base group participating in no group activities, while farmers participating only in events, such as farm tours, were associated with sales revenue gains averaging $169 greater than in the base group. Farmers participating in both meetings and group events were associated, on average, with sales increases nearly $215 greater than those of farmers participating in neither.

The second set of zero-one variables in the program participation block identifies the types of individual program assistance received by a participant during the period of his involvement in a small farm program. Farmers receiving assistance in farm production practices, and those receiving assistance in farm planning or resource management, were associated with farm sales increases $337 to $380 greater than a base group which received only such nonfarm assistance as in garden production or house repair. Those receiving assistance in the use of agricultural agencies or in marketing improvement also earned greater sales volume increases than in the base group, but only in the magnitude of $133 to $201. Regardless

[1] Estimation of several models which included interaction terms (measuring the effect of participants' resources on the responsiveness of farm sales revenue to program participation) provided some additional information on program strategies, but did not basically alter results of the model presented here. Collinearity problems were amplified by inclusion of interaction terms.

of the type of participation, the level of a farmer's interest in the program (as perceived by the field worker and rated on a scale of one to five) strongly affected the outcome associated with that farmer. Sales revenue increases were also positively affected by the length of a farmer's participation in a small farm program.

The fourth group of variables in table 2 de-

Table 2. Effect of Output Prices, Environmentally Related Yield Fluctuations, Farm Resources, Program Participation, Staff Characteristics, and Program Characteristics on Farm Sales Revenue Increases of Participants in Small Farm Programs, Southern Region of the United States, 1977

Variables[a]	Unit	Coefficient (*t*-value)
Price and environmental block		
Variable equals 1 if field staff said indicated factor affected revenue changes, 0 otherwise. (Base: neither prices nor weather.)	output price increase	97.10 (1.76)
	output price decrease	−489.43 (−4.00)
	adverse weather	−418.29 (−5.67)
Farm resource block		
Farm sales volume during the year prior to participation	$1,000	69.39 (16.31)
Off-farm income of family members, 1977	$1,000	26.82 (4.51)
Program participation block		
Group activities: variable equals 1 if farmer participated at least once in indicated activity, 0 otherwise. (Base: neither meetings nor events.)	meeting(s) only	[c]
	event(s) only	169.12 (2.14)
	both meeting(s) and event(s)	214.39 (3.24)
Individual assistance: variable equals 1 if farmer assisted at least once with indicated practice, 0 otherwise. (Base: gardening, home repairs, use of social service agencies.)	crop or livestock production practices	336.88 (4.02)
	farm planning or resource management	382.16 (7.73)
	use of other extension programs or agricultural agencies	132.97 (2.62)
	marketing	201.04 (4.10)
Field staff assessment of farmer interest in program	index 1 through 5 (1 = poor, 5 = excellent)	160.64 (5.73)
Duration of farmer association with program through 1977	years	79.98 (4.20)
Field staff characteristics block		
Age in 1977	years	[c]
Formal education through 1977	years	−25.49 (−3.62)
Experience in farm operation through 1977	years	13.88 (6.54)
Program characteristics block		
Agricultural training for field worker, 1977	days	1.76 (1.66)
Supervisory assistance for field worker, 1977	days	61.22 (5.90)
Influence of field worker ability on effectiveness of assistance received	interaction term[b]	−15.85 (−5.92)
Local supervisor assessment of field worker ability	index 1 through 5 (1 = poor, 5 = excellent)	277.61 (5.76)
Length of employment of field worker through 1977	months	3.46 (4.29)
Equipment and demonstration funds, 1977	dollars	[c]
Farmers assisted per field worker, 1977	number	−5.56 (−3.90)
Intercept		−1,729.47

[a] R^2 = .316. There were 1,874 degrees of freedom for the *t*-tests. Observations were deleted from the sample if there were missing values for any of the independent variables. The dependent variable was expressed in dollars; its mean value was $1,169 and its range was −$1,000 to $3,750.

[b] This variable is a cross-product of the second and fourth variables listed under the program characteristics block.

[c] Not significant at the .05 level in initial regressions and excluded from the model reported.

scribes characteristics of the field staff contacting the farmer. A field worker's success in inducing farm sales volume increases appeared to diminish with formal education, but to increase with years of farm experience. In the field staff characteristics block model (not shown here) significant relationships also were found between field workers' age, sex, and ethnic background and their success at inducing sales revenue improvements. These results suggest that selection of field staff provides program leaders with an important mechanism for influencing program effectiveness.

The final group of variables in table 2, taken from the program characteristics block, reflects the influence of local program resources and field staff training, supervision, and workload on participants' farm sales improvements. Agricultural production training received in the past year by a field worker, and assistance provided by local supervisors and other extension professionals, were positively associated with farm sales improvements realized among farmers contacted by the field worker. Impact of supervisory assistance varied negatively with field workers' ability (as evaluated on a scale of one to five by his local supervisor). That is, another day of professional assistance to a field worker with a low rating (1) was associated, on average, with $48.36 greater farm sales improvements among farmers assisted by that worker. But another day of assistance to a field worker with the highest rating (5) was associated with a $15.02 decrease in farm sales improvements, implying that, at the margin, direct professional assistance may interfere with efforts of higher quality field staff. This suggests that the level of supervisory input into small farm programs ought to be determined at the local level and related to the needs of individual employees.

Field workers' ability itself was positively associated with program success, as was months of staff experience on the job. However, no significant relationship was found between program effectiveness and availability of financial resources to purchase equipment or demonstration supplies. Finally, field staff performance declined only slightly with increasing workload. Field workers reported working intensively with an average of thirty-two farmers during 1977. For every additional farmer assisted by a field worker, average annual sales increases experienced by the farmers associated with that worker declined by $5.56. This implies that within the workload range reported by field staff, program funds might be more effectively utilized if the number of farmers assisted by the average field worker were increased.

Discussion

The results of the unified regression analysis suggest that small farm program success is influenced by a large number of variables, many of which may be controlled by program planning and implementation processes. For example, the results illustrate the importance to program outcomes of policy choices regarding program location and target audience orientation. They also provide guidelines for administrative decisions on field staff employment and on the provision of financial and professional support resources, factors which potentially affect program achievement. Nevertheless, the relatively modest R-square (.316), although not particularly low for cross-sectional models of this type, indicates that much of the variation in program outcomes is determined either by factors for which adequate measures were not achieved or by presently unmeasurable human elements.

Based on the survey responses and an examination of *Census of Agriculture* data, extension small-farm program participants are representative of the approximately 200,000 small farm operators in the South with low total incomes (U.S. Department of Commerce). Currently, the programs serve only a limited proportion of these farm operators. The results show that observed increases in sales revenues are generated in substantial part by the level of participation in, and the quality of, small farm program activities. When such other benefits as improved home food production, increased operator skills, and greater farmer social participation are considered as well, the performance of carefully planned and executed small farm programs appears favorable. Further research to evaluate small-farm program costs and benefits, and to compare these program outcomes to results of alternative assistance approaches, would be useful. However, in the absence of such studies, the present evaluation suggests that expansion of small farm programs merits consideration as a means of assisting limited resource farm families.

An Integration of Industry and Classroom in Graduate Research: A Case Study

Daymon W. Thatch

With students' requests for relevancy and employers' desire to hire students with practical experience, there has been a resurgence of interest in courses and programs both at the graduate and undergraduate level which provide this type of environment for students (Devino, French, Luby, Snodgrass, Thomas). As Snodgrass and others have noted, work experience education has taken a variety of forms and goes by various names. However, almost all involve the concept of off-campus work or study organized by the university with a private business or government agency for which academic credit and/or pay is received by the student.

Off-campus, work-study programs in agricultural economics at an undergraduate level have been fairly popular since the mid-1970s, and several authors have called for more programs (Downey, Epp, and Kneckel). "Few similar programs have been operated at the graduate level." And furthermore, "the benefits would appear to be at least as great for graduate students as for undergraduates" (Devino, p. 580).

The purpose of this paper is to report and evaluate an ongoing graduate research program that has used a number of company and governmental researchers to help students contrast similarities and differences and gain a better understanding of university, industry, and government research.

Philosophical Background

The overall need for an integrated work-study academic program and the virtues of such a program have been well-documented (Stutz and Knapp). As a starting educational position, the author makes three assumptions: first, educational programs should equip graduates with the ability to perform on the job, grow in a given position, and help develop a philosophy that will assure a personally satisfying and productive role in society. Second, education is not a neatly packaged item to be taken home and consumed. Third, within this framework it is the task of educators to develop programs and provide guidance to help meet the needs and desires of students and to provide understanding and ability to function within the given profession.

Industry-Classroom Research Program

In 1971, efforts were initiated to develop an integrated industry-classroom program that would encompass this overall educational philosophy. This paper develops the need, procedure, and preliminary results of the program.

Why Such a Program?

Three facts became apparent to the author after he taught a graduate introductory research methods course for two years. First, an introductory course in research is best taught as a blend of philosophical and analytic approaches which stress fundamentals and common sense; second, although students could learn the concepts and approaches, to understand research they should have some practical applied experience; and third, although students are often technically trained they are unprepared in terms of lines of authority and job expectations for industry or government employment.

In short, although the students receive adequate training in the philosophy, concepts, and approaches to research via formal class lectures, discussions, research report writing, and library searches, they need an applied project that uses the formal ideas in a setting that they will encounter after graduation. The field experience project was initiated to fill this gap.

Field Experience Contacts

In an effort to set up realistic, current, field experience problems, the following procedures were used. The author initially contacted the director of marketing research (or research) of a number of major companies in the local area. The directors were asked, by phone, if they would be willing to spend about two hours in a student experiment to help masters degree candidates understand the nature and problems of industrial or government research. If they were agreeable (and all but one contacted over a seven-year period were) they were asked to submit, on a confidential basis, several past or current projects so that the author could screen them as a possible study project for student research teams.

The second step was for the instructor to meet personally with the researcher at his or her office. This meeting provided a chance to get acquainted

Daymon W. Thatch is an associate professor in the Department of Agricultural Economics and Marketing at Rutgers University.

and assure the researcher that the main purpose of the project was to help students better understand research. In addition, this visit provided the opportunity to explore various approaches and techniques used by individual researchers and to obtain initial information and background data on several potential student research projects. A number of other details also were accomplished at this time, such as checking researcher's availability and obtaining clearance for materials, security passes for students, parking. At the conclusion of the meeting, the researcher was told that he or she would be sent a letter stating the major purpose of the project (an experiment to provide students with insights into company research), confirming date of the student group interview, a copy of the charge given to the group (analyzing and evaluating the company's selected research project), and a statement specifying that materials would be returned and that no written or oral report outside of the classroom would be made with the materials.

Student Projects

From two to four students were organized into research groups using four criteria: selected areas and techniques to be used on masters degree research, general interest, backgrounds, and special skills they possessed. Individual projects were explained to each group. They were given a specific company project and data minus the results and recommendations. In short, each team was given a problem and objectives as stated, along with relevant background and collected data, and asked to do their own analysis and answer specific questions and to draw conclusions to the research and make recommendations.

In addition, each group was given two further tasks. First, they were to develop a background profile on the company and/or division within the company, and, specifically, to pinpoint the company's major goals and overall operating and growth philosophy. This was achieved by evaluating annual reports and other available information used for recruiting. Second, they were asked to obtain information, by interview, on the researcher's philosophy of research and the methods and techniques he or she found most beneficial in doing research.[1]

Before the interviews were held, student groups were given several weeks to obtain information about the companies and to analyze the assigned research project. This time lag allowed the interviews to be held in two to three hours and enabled the students to prepare relevant questions about their specific projects in advance.

Company Interviews

Although cost and time considerations may indicate that a visit of the researcher to the university would be more practical than taking a group of students to the researcher, the latter method was chosen. It was felt that the students would benefit substantially by observing the researchers in their environment, by being exposed to the available facilities, to reference sources, and to the physical position of the researcher in reference to other managers within the company environment. A second benefit of visiting the off-campus research facilities was that in almost all interviews, other researchers involved in the project were asked to join in the meeting. This added insight into the project and exposed the student groups to additional research approaches and philosophies.

In terms of the formal interview, researchers were asked to start by discussing their overall companies' goals and philosophy and then their individual philosophy and approaches to research. These introductory remarks were followed by specific student questions on their assigned project. All of the interview sessions were attended by the instructor-author so that the discussion could be rechanneled if necessary, and, further, to obtain first-hand insights of other researchers' approaches.

Student Group Reports

Computer time and assistance were provided to individual student groups. Although each group team member was asked to analyze, write, and present a part of the final report, it was stressed that the group as a whole was responsible for the overall report and recommendations.

Written reports were submitted to the instructor two days prior to the oral class presentation to allow time for preparation of discussion questions that might not surface during the class. The oral presentation could take any form so long as all the items stated in the project charge were covered and sufficient information was given so that the class could understand the project being evaluated. Questions were encouraged on all phases of the analysis and recommendations.

After the written and oral presentations were given, groups were asked to consider comments and discussion and revise reports, if necessary, so that a final draft could be prepared for submission to the company.

The six steps of the project can be summarized as follows: (*a*) contact researcher for willingness to cooperate in student research experiment; (*b*) arrange a personal meeting with researcher to detail

---

[1] In an introductory research course one of the most difficult tasks is to get students to master the art of defining researchable problems and explicitly stating testable realistic hypotheses. Although a large amount of time in the introductory research methods course is spent on this area, for the field experience project students were given a completed or on-going company research project and asked to evaluate the given research problem and objectives using the formal knowledge obtained in the classroom and in view of company goals and philosophy.

objectives of research experiment and obtain potential company research projects for student groups; (*c*) confirm meeting date, select specific company project that students will evaluate, and set up specific students' project questions; (*d*) meet with researcher(s) at their facilities to answer students' questions on evaluation charges and to obtain company's and personnel goals and philosophies; (*e*) have students submit final written report and orally present results of evaluation and other questions to class for discussion; (*f*) send the confidential student evaluation of the company's research report to company and a letter of appreciation and return the data borrowed to participating company.

Evaluation Comments

The graduate industry-classroom experience program has been in process for seven years. During this period, twenty-three separate student groups have met with both government and business researchers. The results have been excellent and the author concurs with Snodgrass' comments, "There are no significant disadvantages to any party from the offering of work-study programs" (p. 1162), except perhaps in the additional time resources of the teacher. Industry cooperation has been excellent, student enthusiasm high, and from a teaching perspective, students are obtaining applied experience in research and insights into other practical problems they will encounter in business.

In an effort to communicate more systematically the benefits of the program, four areas will be listed: student benefits, instructor benefits, company researcher benefits, and evaluations.

Student benefits include: (*a*) increases interest and motivation by working on meaningful, "real world," research problems—one gains appreciation of alternative research approaches and data sources available; (*b*) helps one to learn self-discipline, responsibility, and how to plan, work as a member of a team, complete a project, and work against deadlines; (*c*) allows one to observe philosophies and goals of companies and researchers to see how these manifest themselves in their research efforts; (*d*) helps one minimize the "culture shock," that is, the way the business research and methods often deviate from the world of academic research; (*e*) develops confidence in one's ability to think, analyze, and evaluate the work of others, and to understand the problems, frustrations, and rewards of research.

Instructor's benefits include: (*a*) helps achieve the learning objectives of the course—in this case, to allow students a chance to evaluate a hand-on practical applied research project and a chance to observe how industry research is conducted by various researchers; (*b*) stimulates the instructor as class becomes more exciting with motivated students studying current "real world" problems; (*c*) obtains insights from interchange with several current applied researchers in terms of current state of the art, available data, and present research needs; (*d*) makes excellent contacts for future class projects, possible student job opportunities, and instructor consulting.

Company-researcher benefits include: (*a*) good researchers seem constantly to desire input and opinions on their current research approaches—this input seems especially valuable when it is relatively free of cost and comes with very little risk of harmful effects; (*b*) researchers also desire the opinions of students as a source of input to add to the sample size of a given survey (often the students of a different generation are "in tune" to ideas or values that may have been overlooked or downgraded by the researcher); (*c*) public relations is important for companies and allowing students to understand company philosophies and goals and to see the effort they expend in research is one valuable component; (*d*) researchers and companies get a look at potential candidates for future positions, and keep in contact with university graduate programs.

Evaluation

In evaluating the above industry-classroom experience approach, only subjective methods have been employed. Student evaluations have been most gratifying in their praise for the project and the insights that have been gained. Positive feedback has been noticeable in the zeal students exhibit in their group assignment and the effort they expend above and beyond that necessary to obtain a grade. Former students on numerous occasions have indicated that the project was one of the highlights of their graduate program.

From the instructor's viewpoint, the industry-classroom experience has more than met the objectives of the course. The uniqueness of this program procedure appears to be the ability to tie together "real world" research and some of its constraints to the formal research methodology taught in an introductory research methods class. This marriage is achieved with minimal direct cost and time away from the classroom. Prescreening of company projects has ensured that the graduate students can understand the projects with very little background and that a variety of project types are available for analysis. Individual projects have been analyzed in consumer product acceptance, product demand, pricing strategies, elasticity evaluation, and investment project alternatives. Analytic techniques have ranged from factor and chi-square analysis to econometric models and evaluations of the major survey methods (mail, personal, and telephone) as well as direct experimental designs.

On the other hand, to be successful, the experience-research project takes considerably more time to prepare than class lectures in research. To be successful, class size must be held to

less than twenty-five students because contact work needed for one instructor to set up experiences becomes overburdening. Furthermore, although the direct travel cost has been fairly small because of the short distances (two to fifteen miles) to the companies, there are other added costs such as telephone, postage, and secretarial time.

High acceptance of the program is indicated by the fact that only one company out of twenty-four has turned down the offer to participate in a project with students. Furthermore, of the ones who have participated, most have said that they look forward to participating in future projects.

The U.S. Pear Market

A. Desmond O'Rourke and Sharif M. Masud

Pears are the second most important deciduous fruit produced by U.S. farmers. They are particularly important in the Pacific Coast states of California, Oregon, and Washington, which have increased their share of total U.S. production in the last quarter century from 89.3% in 1949–51 to 94.5% in 1975–77. About half of all pears are shipped fresh to distant markets, while the remainder are canned or dried so that pear production is of concern to fruit packing, freight and distribution firms throughout the United States, and to processing firms in scattered localities throughout the Pacific Coast states.

About 70% of all U.S. pear production since 1949 has been Bartletts, mostly centered in the Pacific Coast states, especially California. A small proportion of Bartletts are grown in Michigan, New York, and Pennsylvania. Accordingly, a number of previous authors, including Pubols, Edwards, Ricks and Edwards, Kourouklis, and Hoos and Kuznets, have treated Pacific Coast Bartlett pears as a separately identifiable industry. The majority of Pacific Coast Bartlett pears (usually over 70%) each year are processed, mainly in canned form. The remainder are sold fresh.

Most other pear varieties are harvested later than Bartletts and are sold primarily for fresh use. Commonly called "winter" pears, the other main varieties are D'Anjou and Bosc. About 95% of winter pears are grown in the Pacific Coast states, primarily in Oregon and Washington. The share of the national pear market accounted for by winter pears has declined in the last quarter century from 27.3% to 21.2%.

While the general level of pear production has been relatively stable over the last three decades, output has been erratic from year to year. For the 1949–74 period, Masud, O'Rourke, and Harrington found a coefficient of variation of 13.7% for annual production of all U.S. pears and 16.9% for Pacific Bartletts. The number of bearing trees of both Bartlett and other varieties at the 1974 census was the highest for twenty years, but the number of nonbearing trees had declined rapidly since 1964, indicating that the surge of new plantings in the 1960s had not been continued into the 1970s.

Changes in annual average prices generally have been related inversely to changes in production. In the period 1963–68, the weighted average price of all pears exceeded $100 per ton at 1967 prices in five of the six years. In contrast, that price level has been exceeded in only two of the last ten years. Pear producers have been in a quandry about whether to increase or reduce acreage, which varieties to give preference to, whether to increase or reduce processing utilization, or what institutional changes might be made to improve prices and incomes.

Objectives

The objectives of this study were to (*a*) estimate annual farm level prices of Pacific Coast Bartlett pears in processing and fresh markets, (*b*) determine the relationship between demand for Bartlett pears and that for other Pacific Coast pears and other U.S. pears excluding Pacific Coast, (*c*) determine the optimum allocation of a predetermined quantity of Pacific Coast Bartlett pears between fresh and processing uses, and (*d*) predict the price impact of possible future developments in the U.S. economy and the U.S. pear industry.

The last study of the U.S. pear industry to take such a comprehensive view was that by Pubols, who used data up to and including 1954. Pubols studied the factors affecting the annual average price of all Pacific Coast pears, fresh Pacific Coast Bartlett pears, canned Pacific Coast Bartlett pears, Pacific Coast pears other than Bartlett, and pears other than Pacific Coast. All variables were converted into first differences of logarithms and price equations estimated using ordinary least squares. Pubols analyzed relationships for 1925–42, 1942–54 and for the entire period 1925–54. In general, all prices were negatively and significantly affected by own-quantity and 1 June stocks of canned pears, and positively affected by income. Pubols found little evidence of mutual impact of other U.S. pear production on Pacific Coast pear prices, but Pacific Coast Bartlett prices were significantly affected by production of other Pacific Coast pears.

We were interested in seeing whether the relationships reported by Pubols still held in the U.S. pear industry more than two decades later. However, because of our broader objectives, the impact of inflation since 1954, and the need to take into account simultaneity in price determination and

---

A. Desmond O'Rourke is an associate professor of agricultural economics at Washington State University, and Sharif M. Masud is an assistant professor at Morningside College, Sioux City, Iowa.

Scientific Paper No. 5359. Work was conducted under project 0418, College of Agriculture Research Center, Washington State University.

processing allocation, our model formulation differed considerably from that used by Pubols.

Edwards' 1965 study, which looked separately at demand for Bartlett pears from California and those from Oregon and Washington, concluded that they were a homogeneous commodity in terms of market behavior. Ricks and Edwards were concerned primarily with the Pacific Coast Bartlett pear industry. Kourouklis mainly investigated intraseasonal aspects of demand for Oregon Bartlett pears. Hoos and Kuznets' contribution has been an annually updated formula for predicting the FOB price of canned Bartlett pears, which formula is used in price negotiations between growers and canners. Thus, our model differs from the above in period covered, basic goals, and intended use of the results.

Economic and Statistical Model

Because our study focused on determination and prediction of price and of product allocation at the farm level, our economic model did not attempt to analyze the entire pear production and marketing system. It was necessary to assume that supply in any year was predetermined and that the relationship between farm level demand and retail demand was constant over time. The U.S. Department of Agriculture series on canned pears show that for the five-year intervals 1964–68, 1969–73 and 1974–78, marketing margins averaged 77.8%, 78.0%, and 78.2% of retail price. Accordingly, our assumption about the farm-retail relationship appears reasonable.

Originally, following Pubols, it was assumed that allocation of Pacific Coast Bartlett pears, and prices for Pacific Coast Bartlett pears, other Pacific Coast pears, and other U.S. pears would be determined simultaneously. If price of processing Bartletts rose, the quantity allocated to processing would rise and the supply available for fresh market fall, thus affecting fresh market price. In a similar manner, it was hypothesized that the demand for fresh Bartlett pears would be interrelated with the demand for other Pacific Coast pears and other U.S. pears which go primarily to the fresh market. However, since the period studied by Pubols, Pacific Coast Bartletts have become increasingly dominant in the national pear market. Accordingly, in preliminary analysis, we found that for the 1949–77 period the significant influences were unidirectional. Bartlett pears affected the demand for all other pears but not vice versa.

The economic model which best described the U.S. pear industry included a demand and an allocation equation for both fresh and processed Pacific Coast Bartlett pears, a demand equation for other Pacific Coast pears, and a demand equation for other U.S. pears—six equations in all, as follows:

Pacific Coast Bartlett Demand Equations

(1) Processed:

$$Y_1 = f(Y_3, X_1, X_2),$$

(2) Fresh:

$$Y_2 = f(Y_4, X_2, X_3).$$

Pacific Coast Bartlett Allocation Equations

(3) Processed:

$$Y_3 = f(Y_1, Y_2, X_4, X_5),$$

(4) Fresh:

$$Y_4 = f(Y_1, Y_2, X_4, X_5).$$

Other Pear Demand Equations

(5) Other Pacific Coast:

$$Y_5 = f(X_1, X_2, (X_4 + X_6), X_7),$$

(6) Other U.S.:

$$Y_6 = f(X_2, (X_4 + X_6), X_7).$$

The Ys indicate endogenous variables and the Xs, predetermined variables. To remove the influence of changes in population and general price level over time, all quantity variables were converted to tons per 1,000 people and all price and income variables were suitably deflated, grower prices by the wholesale price index, personal disposable income per capita by the consumer price index: Y_1 is grower price of processed Pacific Coast Bartlett pears ($/ton); Y_2, grower price of fresh Pacific Coast Bartlett pears ($/ton); Y_3, quantity of Pacific Coast Bartlett pears allocated to processing; Y_4, quantity of Pacific Coast Bartlett pears allocated to fresh; Y_5, grower price of other Pacific Coast pears ($/ton); Y_6, grower price of other U.S. pears ($/ton); X_1, stocks of canned pears, June 1; X_2, disposable personal income per capita, U.S.; X_3, quantity of U.S. fresh nectarines; X_4, total production, Pacific Coast Bartlett pears; X_5, trend (= 0, 1949, = 1, 1950 . . .); X_6, total production, other Pacific Coast pears; and X_7, total production, other U.S. pears.

The price-quantity relationship specified are what economic theory would lead us to expect. Previous research has generated empirical evidence of a negative influence of quantities produced, allocated, or in stock on price. Pubols and Kourouklis have demonstrated the positive influence of income on demand. Our preliminary analysis suggested the influence of a competing seasonal fruit, fresh nectarines, on the price of fresh Pacific Coast Bartletts and of a positive trend factor in the allocation of Bartlett pears to processed uses.

The marketing season for fresh nectarines has more overlap with that of fresh Bartlett pears than

does any other competing fruit. In preliminary analysis the influence of fresh apple supplies was found not significant. The percentage of the Bartlett pear crop allocated to processing has shown an upward trend in the period studied.

Our model consisted of four demand equations, one allocation equation and one identity because with X_4 predetermined, once Y_3 is known, Y_4 is equal to $X_4 - Y_3$. Equations (1) through (3) were estimated using two stage least squares (TSLS), and equations (5) and (6) using ordinary least squares (OLS) under the usual assumptions about the properties of the error terms. All the equations in the simultaneous part of our system were overidentified.

Annual data for the years 1949–77 were used in statistical estimation. Data were drawn from publications of the U.S. Departments of Agriculture and Commerce and of the relevant state agencies. A complete listing is available from the authors.

Statistical Results

In general, the results of the statistical estimation were satisfactory by the usual measures of level of significance and conformity of signs to theoretical expectations (table 1). The value of the t-statistic for each coefficient is reported, although in the case of the TSLS equations, they can be used as an approximate indication of significance. Perhaps the most surprising results were those for income. For both fresh and processed Bartlett price equations, the influence of income was small and positive but the t-value low. For other Pacific Coast pears, the income coefficient was negative and significant at the 5% level; for other U.S. pears, it was negative but not significant. This contrasts with Pubols' findings of a significant positive influence of income on the price of each type of pear.

Some explanation of this discrepancy is in order. Pubols' data covered the period 1925–54, whereas our study examined only postwar conditions for 1949–77. Between 1949 and the mid-1960s, the supply of both Bartlett pears and of all other pears declined so that real price rose while income rose. However, since the mid-1960s, supplies of pears have been rising and real price falling at the same time that real income has continued to rise. The decline in real price has been greater than could be explained by the increase in quantity alone. The income variable may be acting as a proxy for both income effects and changes in tastes, consumer and retailer preferences, etc., which have adversely affected the demand for pears. For example, with a decline in the birth rate since the mid-1960s, a number of major processors in Michigan have discontinued buying pears completely.[1]

When we reran our model for the subperiods 1949–67, 1955–77, and 1961–77, the signs and magnitudes of all coefficients except income were stable. However, the income coefficients on processed Bartlett pears, other West Coast pears, and other U.S. pears became either less positive or more negative the more recent the period studied, but only significantly negative in the case of other West Coast pears. Accordingly, we concluded that our results for the 1949–77 period, by providing most degrees of freedom, and by covering both rises and declines in pear production, gave us the most generally defensible model of the U.S. pear industry for both forecasting and allocation purposes.

June 1 stocks of canned pears strongly influenced the price of processed Bartletts, and fresh nectarine supplies, that of fresh Bartletts. Other Pacific Coast and other U.S. pear prices were significantly influenced by total Pacific Coast and other U.S. pear supplies. Other Pacific Coast pear price was also sensitive to 1 June stocks of canned pears, although the actual process of influence probably is felt indirectly through the effect of canned stocks in the Bartlett pear market.

Price Flexibilities and Elasticities

Price flexibilities derived from the demand equations were estimated for the mean values of the relevant variables and for the most recent (1977) values, enabling us to compare results across varieties and over time (table 2). In all cases, own-price flexibility of demand was negative and significant. Because pear prices for all varieties tend to approach the same general level from year to year, price flexibility at the mean was greatest where per capita consumption was greatest, ranging from almost 1.958 for processed Pacific Coast Bartletts to 0.412 for other U.S. pears. Flexibility was greater in 1977 than at the mean value for processed Pacific Coast Bartlett pears but less for all other pears.

The price flexibilities for both fresh and processed Pacific Coast Bartlett pears were greater than unity and greater than those reported by Kourouklis although still of the same relative magnitudes, suggesting that diversion of Bartlett pears from processing to fresh markets would increase total revenue to growers.

Income elasticities for both fresh and processed Bartletts were positive and increasing over time although not statistically significant. In contrast, income elasticities for other West Coast pears and other U.S. pears were negative and becoming more so over time. Pubols found large positive income elasticities for all four categories of pears.

Price of processed Bartlett pears was becoming more sensitive to the level of June canned pear stocks and price of fresh Bartlett pears to the sales of fresh nectarines, which have risen rapidly in recent years. The elasticity of quantity processed was greater for processed price than for fresh price, the former positive, the latter negative (table 3). Quantity processed was significantly affected by total production of Bartletts with an elasticity close to unity.

Forecasting Price

A major objective of the study was development of a model which would predict the price of the different categories of pears in the light of changes in population, per capita income, and production of pears. Such a model would be useful to growers and processors prior to harvest in making decisions about price or allocation in any year and would also be capable of predicting the impacts of longer-term changes in economic conditions or production.

The derived reduced form of equations (1) through (4) was used for forecasting because it not only takes account of overidentifying restrictions, but also preliminary experiments on past data showed better prediction results from the estimates of derived reduced form than from the unrestricted reduced form. The OLS estimates were used for forecasting in equations (5) and (6).

In general, tests of goodness of fit of the estimated functional forms for past data were better for quantity than price equations.[2] For variables Y_1 through Y_8, the mean absolute percent error was 13.4, 14.9, 3.4, 9.7, 17.0 and 9.2, respectively. The forecasting equations were also applied to data for 1978, outside the range of data used in estimation (table 4). Our results were encouraging. Errors in forecasts were much below those experienced for the historical period analyzed. This suggests that in 1978, processors and growers agreed on a processing price close to that needed to attract adequate supplies to processing. In general, it appears that our model can estimate fairly precisely the likely allocation of Bartlett pears and the general direction

[2] These tests do not measure the extent of the variation in the price forecasts which is due to variation in the exogenous/predetermined variables. It is hoped in subsequent work to apply the method suggested by Feldstein for measuring that source of variation.

Table 2. Price Flexibilities of Demand Computed at Mean Values and at 1977 Values, for Pears of Different Variety and Origin, 1949 to 1977

Type of Flexibility	Value at Mean	1977 Value
Price with respect to own quantity:		
Processed Pacific Coast Bartletts	−1.958*[a]	−3.187*
Fresh Pacific Coast Bartletts	−1.315*	−1.070*
Other U.S. pears	−0.412*	−0.270*
Price with respect to income:		
Processed Pacific Coast Bartletts	0.193	0.390
Fresh Pacific Coast Bartletts	0.479	0.847
Other Pacific Coast pears	−0.777*	−1.410*
Other U.S. pears	−0.386	0.459
Price with respect to 1 June canned stocks:		
Processed Pacific Coast Bartletts	−0.407*	−0.676*
Other Pacific Coast pears	−0.283*	−0.423*
Price with respect to fresh nectarine sales:		
Fresh Pacific Coast Bartletts	−0.424*	−1.402*

Table 3. Elasticities of Processing Allocation Computed at Mean Values and at 1977 Values, Pacific Coast Bartlett Pears, 1949 to 1977

Type of Elasticity	Value at Mean	1977 Value
Processing allocation with respect to:		
Processed Bartlett price	0.392	0.240
Fresh Bartlett price	−0.352	0.247
Total production, Pacific Coast Bartletts	0.933*[a]	0.874*

[a] *, is derived from coefficients with t-value > 2.0.

of change in prices of all four pear categories discussed.

Optimum Allocation of Pacific Coast Bartletts

Pear growers are concerned about how to allocate a given crop between fresh and processed uses to maximize their gross revenue. Our model can be used to identify such an optimum point for growers, recognizing that processors, consumers, and society as a whole will not also be at an economic optimum at that point.

Defining V, the total returns by

$$\text{Max } V = \hat{Y}_1\hat{Y}_3 + \hat{Y}_2\hat{Y}_4,$$

subject to demand functions (1) and (2) and the identity, $Y_4 = X_4 - Y_3$, the problem can be reformulated to solve for Y_3, the estimated processing allocation that would earn a maximum total return to growers. On average, the optimal solution for growers would require a reduction of processing allocation by about 9% and an increase in the smaller fresh allocation by almost 26%. The model suggests that total sales revenue to growers over the entire period could have been increased by 4.6%, or 60 million 1967 dollars above that actually achieved. While this gain is substantial, many growers would be reluctant to change established institutions and practices in order to achieve it. However, the optimal allocation was becoming increasingly more beneficial in recent years. In the first eight seasons of the 1970s, optimal revenue exceeded actual by 10.8%. This outcome is consistent with the results reported in table 2, which showed the price flexibility of processed Bartletts increasing and of fresh Bartletts decreasing.

Summary and Conclusions

Our econometric model suggests that average income elasticities in the 1949–77 period were low for Bartletts and negative for all other pears. In contrast, for the earlier 1925–54 period, Pubols found positive and significant income elasticities for all four categories of pears studied. The indicated negative income elasticities logically can be expected to discourage expansion of production of varieties other than Bartletts in the Pacific Coast states and in the rest of the United States.

Our finding of higher price flexibilities for processing Bartletts than for fresh Bartletts suggests that grower returns could be increased by allocating a greater proportion of the total Bartlett crop to fresh market. Our model can also be used to forecast price and allocation of pears for given levels of the predetermined variables, and to determine the allocation of Pacific Coast Bartletts which would maximize sales revenue to growers. The model should be both a useful tool for policymakers and of practical value to decision makers in the pear industry.

The Impact of Women's Time Allocation on Expenditure for Meals Away from Home and Prepared Foods

Barbara J. Redman

Increased attention has been devoted in recent years to the allocation of women's time between market production, household production, and leisure. This allocation of time should have direct consequences for food preparation and consumption, because food preparation accounts for much of the time spent in household production. Despite changing sex roles, women still make most of the food-related decisions and perform much of the food selection and preparation activities. Therefore, a household's expenditure on ready-prepared foods and meals consumed away from home, as requiring the least amount of homemaker's time, should be inversely related to the amount of a woman's time allocated to household production and to those factors affecting such allocation.

The purpose of this article is to test the hypotheses advanced by Gronau, who extended Becker's time-allocation analysis to a woman's household labor time versus leisure time versus market labor time. These hypotheses are:

(*a*) If an employed woman's wage rate increases or an unemployed woman's nonwage income (including a husband's income) increases, the time that woman spends on household production will decrease.

(*b*) As children grow older, the real wage of the mother in terms of market substitutes increases (older children require less parenting time), which implies that household production time decreases and market time increases. Employed mothers substitute between market and leisure time, rather than market and household time.

(*c*) A woman's time spent on household production bears a negative relationship to the level of her education.

(*d*) Among employed women, the woman's age positively affects time spent in household production and leisure and negatively affects time in the market; among unemployed women, age negatively affects time spent in household production.

From Gronau's analysis, one would predict that family income, college education (of the woman), and age of children bear a positive relationship to expenditure on prepared foods and meals away from home. As only about a third of U.S. households contain wives employed outside the home, age and prepared foods should be positively related. The case for meals away from home is not entirely analogous, because this form of food consumption more nearly reflects changing lifestyles and values, which the younger women should adopt more readily. One would expect employed wives to spend less time on food preparation and therefore more money on prepared foods and meals away from home than unemployed wives.

Prochaska and Schrimper tested Becker's model in relation to the number of meals consumed away from home. They constructed a variable for wage of wife, as a function of age and schooling, to measure the opportunity cost of a homemaker's time. In their model, a differential effect for this variable was permitted according to whether or not the homemaker was employed outside the home. However, they were interested primarily in whether or not the opportunity cost of time was significant for either group of homemakers. They also included the effects of family income, family composition, family size, race, region, and urban/rural/farm residence.

The present study tests Gronau's hypotheses, which distinguish between three uses of time and consider the differential effects of household characteristics on these uses. Predictions more precise than Prochaska and Schrimper's concerning food consumption as an aspect of household production are thus permitted. In particular, age and schooling of the woman are included explicitly in the present model. Following Prochaska and Schrimper, race, region, and metropolitan/urban/rural residence were added as explanatory variables. Particularly because reported data consisted of expenditures on, rather than quantities of, food, dummy locational variables were desirable as controls for geographic price variation. Prochaska and Schrimper, using quantity data, analyzed income elasticities; the use of expenditure data in the present study permits estimation of the dollar influence of the various characteristics on industry sales.

Data

Data from the diary portions of the Bureau of Labor Statistics 1972–73 and 1973–74 Consumer Expenditure Surveys provided the 9,392 observations used in multiple regression analysis. Households excluded were those that did not report for both years, that incompletely reported income, and for whom single-valued family size, age, and education information was not given. For each dependent variable, two regression models were developed (table 1), one to test the effect of family size per se and the other to test family composition. Where family size in the one regression was significant, the other regression served to locate the source of this observed effect as well as to test the Gronau hypotheses.

Total money income of the consuming unit in the previous twelve months, family size, region, age of the woman, and racial identity were obtained directly from the BLS tapes. From the ages of children given, three variables were constructed for number of preschool children (age under 6), number of elementary school children (age 6–12), and number of high school children (age 13–18). Metropolitan areas were defined as SMSAs of 400,000-plus population; urban (outside SMSAs) and rural areas were as defined by the BLS. If the head of the household was married and there was a positive income of spouse reported, the wife was presumed to be employed outside the home and the employment dummy variable took on a value of one. The presence of a college education of the woman meant that the woman had completed at

least some college. Meals consumed away from home included breakfast, lunch and dinner, but excluded school lunches and other meals such as board plans. Prepared food included prepared flour and cake mixes, bakery products, and canned or frozen meats and dinners.

Results

As the hypotheses predict, family income has a positive effect on meals consumed away from home. Family size in the aggregate has a negative effect, probably due to the financial burden of frequent meals out. However, the coefficients on the ages of the children support Gronau's hypothesis. Families with preschool children spent significantly less on meals out than other families, and families with progressively older children spent (significantly) progressively more on meals away from home. At least two explanations exist for this: the hypothesized increase in the real wage of the mother, and relevant characteristics of small children themselves such as a smaller stomach capacity and possible behavior problems in restaurants. Since the pattern is progressive through the older age groups, however, it is likely that the real wage effect holds.

Households with older women spent significantly less on meals out than do those with younger women, probably due to differences in life styles and values. The presence of an employed wife was not significant. However, because this variable referred only to wives and 35% of the sample was unmarried, effects of employment outside the home may have been obscured by similarities between employed wives and employed unmarried women with respect to eating out. The intercorrelation of wife employment and family income ($r = .37$) also may contribute to the insignificance of the former.

Households in metropolitan areas spent significantly more than average, and those in rural areas significantly less, on meals away from home. This probably reflects availability and prices of eating establishments. Other findings included lower expenditures by blacks and by households in the North Central region. Although the R^2 were not extremely high, they were comparable to those obtained by Prochaska and Schrimper.

In the case of prepared foods, as predicted, family income, employment of wife, family size, children of all ages (but with the same graduated effect noted above), and age of the woman were all positively significant. Blacks spent significantly less on prepared foods, which was consistent with the findings on meals away from home. Urban households spent more than households elsewhere on prepared foods; perhaps metropolitan households eat out while urban households (due to lesser availability of eating establishments) solve the time allocation problem by purchasing ready-prepared foods for home consumption. The woman's college education had a surprising negative effect. It is difficult to ascertain whether this is due to statistical effects (although intercorrelations among independent variables were generally not large) or whether college-educated women in fact spend less on prepared foods than other women. As they did not spend significantly more on meals away from home, it is unlikely that the prepared-foods coefficient is related to total home food expenditure. One possible explanation is that the college-educated are more nutrition-conscious and thus would be more selective of ingredients than is possible with many prepared-food purchases. As only a limited range of variables on women's characteristics were available, data did not permit further exploration.

Conclusions

The results indicate that characteristics of women which affect the allocation of their time to household production do significantly influence their households' expenditures on foods requiring relatively little preparation time. However, the effects on prepared foods consumed at home and meals away from home differ in a few respects. The family size and metropolitan/urban/rural differences already have been noted. Younger women eat out; older women buy prepared foods for home consumption. Employed wives buy more prepared foods but not more away-from-home meals, while education appears to decrease the demand for prepared foods.

These results may have considerable importance for the restaurant, fast-food, and prepared-food industries. The restaurant and fast food industries should cater to young families without small children, while the prepared-food industries should orient themselves to the older families where the wife has returned to the labor force. Since household expenditures on these food items represent sales receipts for these industries as a whole, the coefficients reported represent the dollar influence of various characteristics of women on industry sales. In particular, as increasing numbers of women undertake employment outside the home and as family incomes rise even further, these industries should experience increased sales and take on increased importance in the national economy.

Land Treatment of Municipal Wastewater in Small Communities

C. Edwin Young and Donald J. Epp

A sizable portion of the budget in many small communities is devoted to the treatment of wastewater (more commonly called sewage). A community of 5,000 persons may spend more than $150,000 annually (adjusted to a June 1978 base) for secondary wastewater treatment using trickling filters, a low-cost alternative for this size community. If, in addition, advanced wastewater treatment (AWT) is required to remove nutrients, such as phosphorus and nitrogen, in order to meet surface water quality standards, annual costs can increase to $391,000 and $443,000, depending on whether treatment techniques such as lime addition and nitrification-denitrification are used (Young 1978). These processes can remove approximately 90% of the phosphorus and nitrogen, respectively, in municipal wastewater. As national policies to improve the quality of surface waters are implemented, increasing numbers of small communities in rural areas are being required to increase the level of treatment to include AWT. Research reported in this article shows that land treatment (LT) of municipal wastewaters can meet these increased surface water quality standards for about half the cost of the AWT alternative. Because the economies of size are dramatic for all types of small-scale wastewater treatment facilities, the per unit costs of treatment may be reduced further if food processors or other industries contribute wastewater to the system (Rossi, Young, Epp). Thus, the efforts to broaden the economic base of small, rural communities may be affected by the results reported here.

In addition to its impact on resource use and community development, there also are economic impacts on farms receiving LT. These effects, of course, vary by farming region. The optimal (cost-minimizing) crops to be grown on LT areas vary from one type of farming region to another due to climatic and crop differences as well as differences in the type and number of livestock raised. Likewise, the equitable financial arrangement between the wastewater treatment authority and the farm operator may differ between regions as the value of supplemental water and nutrients varies.[1] While additional research is needed to refine the regional differences, results of such research are reported for enterprise combinations, soils, and climate typical of much of the middle Atlantic region.

The federal government has recognized the use of LT systems in solving problems of water pollution in the 1972 and 1977 amendments to the Federal Water Pollution Control Act (P.L. 92-500 and P.L. 95-217). The 1972 amendments called for nationwide improvement of the level of wastewater treatment, provided subsidies to pay for up to 75% of construction costs, and encouraged construction of revenue-producing facilities that provide for recycling potential sewage pollutants through agricultural and silvicultural production. Further support for LT was contained in P.L. 95-217, which made receipt of a federal construction subsidy contingent upon explicit consideration of innovative and alternative treatment and provided an additional 10% construction subsidy for these techniques. An innovative or alternative system is deemed cost effective if its costs are not more than 115% of the least costly treatment alternative available.

Land treatment as a technique for achieving AWT of municipal wastewater is examined in this paper. First, the LT process is described and treatment costs are simulated for community sizes ranging from 5,000 to 250,000 persons. Then the effect of crop selection on LT systems is analyzed followed by a discussion of the impact of federal construction subsidies on LT costs.

Land Treatment Processes

Land treatment refers to the controlled discharge of partially treated sewage effluents onto land to remove contaminants from the water. The soil and/or agricultural crops or forests absorb and filter ni-

C. Edwin Young is an agricultural economist with the Natural Resource Economics Division, Economics, Statistics, and Cooperatives Service of the U.S. Department of Agriculture, stationed at Pennsylvania State University. Donald J. Epp is an associate professor of agricultural economics at Pennsylvania State University.

This paper is authorized for publication as paper no. 5823 in the journal series of the Pennsylvania Agricultural Experiment Station.

[1] One further aspect of research on LT that is of particular interest to production economics theorists is the negative price associated with the nutrients and water as inputs to a farm business. Because alternative disposal techniques frequently cost a great deal more than application to farmland, the opportunity cost of the wastewater inputs is negative meaning that the profit-maximizing level of use is in Stage III of the production function. Research on land treatment of wastewater provides an opportunity for empirical testing and demonstration of a phenomenon that differs from conventional production theory.

trates, phosphates, organics, and other elements from the effluent. Generally, a portion of the vegetative cover is harvested to remove nutrients from the site and to provide a revenue to offset partially the treatment costs. The design and operation of LT systems are described in two reports from the U.S. Environmental Protection Agency (1975, 1977).

The three basic ways of applying wastewater to land for treatment and removal of pollutants are irrigation, overland flow, and rapid infiltration. The most common method is irrigation, using conventional irrigation techniques such as center pivot, solid set, border strip, and ridge and furrow irrigation techniques. An agricultural or silvicultural crop is usually grown in conjunction with an irrigation system. In an irrigation system, the wastewater is applied at a rate of 1 to 6 acre-inches of wastewater per week and the water is purified as it passes through the root zone of the vegetative cover. Irrigation systems remove 85% of the applied nitrogen and 80% to 99% of applied phosphorus. Overland flow refers to the application of wastewater onto an impermeable soil with a slope of 2% to 4%. The water flows down the slope with the renovation of the wastewater occurring in the upper 1 to 2 inches of soil. Approximately 70% to 90% of nitrogen and 40% to 80% of phosphorus are removed. Application rates range from 2 to 9 acre-inches per week for overland flow. The final method of land treatment of wastewater is rapid infiltration where large quantities of water (4 to 120 acre-inches per week) are applied to a highly permeable soil such as sand or gravel. Treatment efficiency is lower for this type of system. Removal rates are less than 50% for nitrogen removal and range from 60% to 95% for phosphorus removal. (This analysis concentrates on the irrigation alternative. Individuals interested in the two other methods of land application are referred to Young, 1976.)

Land treatment costs are influenced by numerous interrelated variables. Design factors which the community has some control over include: (*a*) degree of pretreatment, (*b*) effluent transmission (pumping) costs, (*c*) land costs, (*d*) annual rate at which water is applied to the site, (*e*) type of vegetative cover, and (*f*) restrictions placed on the system to prevent the spread of disease organisms. These variables may be traded off against one another in order to minimize treatment costs. For example, a community can pump its wastes further from the city to obtain less costly land. Alternatively, land requirements can be reduced by selecting a crop or vegetative cover that can be irrigated at a higher annual rate.

The community will have less control over variables influencing LT costs, such as: (*a*) rainfall, (*b*) soil type, (*c*) topography, (*d*) length of growing season, and (*e*) local citizens' attitudes toward the installation of an LT system. The community also has little control over the institutional setting in which it must operate, such as, the legal power to enter into joint wastewater authorities with other municipalities, to contract land for land application services, or to acquire title to land for wastewater irrigation sites. About the only control the community has over these factors is selection of an appropriate site and public education.

An important factor affecting the cost and performance of a land application system is the particular crop or crops which are selected for wastewater irrigation. Crop selection affects the revenue which can be generated from sales of the agricultural crop which is irrigated. Certain crops are capable of being irrigated for longer periods of time throughout the year which eliminates the need for storing the wastewater and the associated costs of storage and applying the stored wastewater to the land at a later date. Thus, the longer the irrigation season, the lower are the costs of wastewater irrigation. Finally, the amount of wastewater that can be applied within a specified time period, such as one week, to a crop also affects the costs of the land application system. The more wastewater that can be applied while maintaining the crop yield and renovative capacity of the land application system, the lower the cost will be. Certain crops, such as grasses, tend to remove nutrients while accepting higher quantities of wastewater.

A wide variety of cropping activities has been suggested or utilized for land application systems. Crops include forages such as reed canarygrass, bermuda grass, and alfalfa hay; grains such as corn, barley, and sorghum; cotton; and silvicultural crops such as hardwood forests and pine forests. Additional experiments have been performed with land application on uncultivated fields or natural vegetation. In this analysis, we limit the crops examined to those for which we have experimental results showing the effect on crop yield and performance of wastewater irrigation. Thus, our results apply to data from experiments at Pennsylvania State University as reported by Kardos et al. This is the only information of which the authors are aware that pertains to crop yields and renovative capacities for wastewater application performed over a long period of time (fifteen years).

The cost effectiveness of LT relative to alternative AWT options has been analyzed using engineering simulation models and statistical analyses of existing facilities. Pound, Crites, and Smith compared simulated AWT costs with LT costs for three sets of assumptions (favorable, mildly favorable, and unfavorable). Alternatively, Young (1978) identifies conditions which influence the relative cost effectiveness of LT. Williams, Conner, and Libby compared six small operating LT systems with four conventional treatment systems. Young and Carlson, using regression analysis, compared twenty-one irrigation systems with thirty-one AWT systems. Each of these studies reached a similar conclusion. Land treatment is cost effective for small facilities—those capable of treating less than five to ten million gallons per day (mgd) of wastewater.

Method of Analysis

The cost of land application of wastewater (CLAW) simulation model is used to study the design of land application systems in the following analysis. The CLAW model is a computer simulation model which can be used to design land application systems capable of treating from 0.1 mgd to 100 mgd of wastewater per day using six alternative application techniques. The application techniques include solid-set irrigation, center pivot irrigation, border strip irrigation, ridge and furrow irrigation, overland flow, and infiltration basins. The model as described by Young (1976) has six basic steps: preapplication treatment, effluent transmission, wastewater storage, application of the wastewater, cropping, and recovery of the renovated wastewater if desired. Simulation was selected as the mode of analysis due to the extreme nonlinearities associated with land application systems which will be evident in the data presented in the following section. By altering the data read into the model, the results can be generalized to a wide variety of situations.

Land Treatment Costs

Even though land treatment is a recycling process and produces a saleable by-product in many instances, it is still a costly undertaking. Cost estimates for solid-set (SSI) and center pivot (CPI) irrigation of reed canarygrass are illustrated in table 1. Based on the experimental results at Pennsylvania State University (Kardos et al.), the cost estimates assume that canarygrass is irrigated year-round. The estimates apply to facility sizes ranging from 0.5- to 25-mgd treatment capacity. The cost estimates range from $175,200 per year for the 0.5-mgd CPI system to $3,614,500 per year for the 25-mgd SSI system. Examination of the cost estimates in table 1 reveals that there are significant economies of size on a per mgd treatment basis. Costs fall from $372,000 per mgd for a 0.5-mgd SSI facility to $145,000 per mgd for the 25-mgd facility. Most of the advantages to increasing facility size are reached when the design capacity exceeds the 5- to 10-mgd range.

For explanatory purposes, the total cost estimates in table 1 are divided into capital, operating, and net crop revenue. The capital and operating cost estimates refer to the operation of the irrigation system, while the net crop revenue estimates apply to the net profit (or loss) from the cropping enterprise. Capital costs make up the largest proportion of the total cost estimates for both types of irrigation facilities. For SSI systems capital costs comprise 75% to 76% of annual total costs, while capital costs comprise 69% to 73% of the annual total costs for CPI systems. Conversely, the operating costs for the CPI systems are slightly higher than those for the SSI systems.

Table 1. Costs (1978) of Year-Round Wastewater Irrigation of Reed Canarygrass

Facility Size (mgd)	Solid-Set Irrigation		Center Pivot Irrigation	
	Annual	Per mgd	Annual	Per mgd
	Total Costs ($)[a]			
0.5	186,300	372,000	175,200	350,400
1.0	274,000	274,000	249,700	249,700
5.0	882,500	176,500	750,800	150,100
10.0	1,588,000	158,800	1,315,400	131,500
25.0	3,614,500	145,000	2,906,400	116,300
	Capital Costs at 6% for Twenty Years ($)			
0.5	141,600	283,200	127,500	255,000
1.0	206,200	206,200	177,700	177,700
5.0	665,700	133,100	519,500	103,900
10.0	1,201,400	120,100	905,600	90,600
25.0	2,752,800	110,100	2,002,100	80,200
	Operating Costs ($)			
0.5	50,200	100,400	53,200	106,400
1.0	78,800	78,800	83,000	83,000
5.0	272,100	54,400	286,500	57,300
10.0	497,100	49,700	520,400	52,000
25.0	1,137,900	45,500	1,180,500	47,200
	Net Crop Revenue ($)			
0.5	5,500	11,100	5,500	11,100
1.0	11,100	11,100	11,000	11,100
5.0	55,300	11,100	55,300	11,100
10.0	110,500	11,100	110,500	11,100
25.0	276,300	11,100	276,300	11,100

[a] Total costs are the sum of capital and operating costs less net crop revenue.

To understand better the impact of crop selection on the cost of land application facilities, the profits and loss from the cropping enterprise were separated from the irrigation costs. In this example, reed canarygrass is irrigated year-round. Based on demonstrated results reported in Kardos et al., it is assumed that the reed canarygrass can be irrigated throughout the year and still maintain a high degree of renovation of the wastewater which is percolating through the soil profile. Two important features of the profit from irrigating reed canarygrass should be noted. First, it is assumed that there are no economies or diseconomies of size associated with the cropping operation. Second, it is assumed that the reed canarygrass is harvested as silage and has a value of $15 per ton. This value was based on nutrient content and on experimental feeding of reed canarygrass to cattle at Pennsylvania State University (Bradley).

Alternative Cropping Patterns

Other crops for which data exist on response to wastewater irrigation include alfalfa, corn, and several types of forests and other uncultivated areas. The annual total cost estimates for four crops at three application rates and various lengths of irrigation season are presented in table 2 for 1-mgd SSI systems. The SSI system was chosen for this analysis because it is more frequently used in operating systems even though our analysis shows CPI systems to be less expensive. Similar results will occur if CPI systems are substituted for SSI systems. Comparison of the results in this table will provide generalizations for the impact of wastewater irrigation in various regions of the country. It should be noted that the price for which crops may be sold and the renovative capacity of the predominant soil types will vary depending upon local conditions. Thus, the results are suggestive and not conclusive.

Table 2. Annual Total Cost Estimates (1978) for Alternative Cropping Patterns for a 1.0 mgd Solid-Set Irrigation System

Crop	Weeks of Irrigation	Application Rate (inches/week) 1	2	3
		---------	($)	---------
Reed canarygrass	52	347,300	274,000	249,100
	48	385,900	306,200	279,400
	40	466,300	369,700	338,000
	32	560,700	438,500	399,200
Alfalfa	40	429,800	343,800	320,800
	36	470,400	374,300	349,000
	32	514,900	406,200	377,700
Corn	40	445,000	357,800	340,000
	36	487,400	389,800	370,300
	32	543,000	423,700	401,700
	28	587,100	460,900	435,300
Forest	52	412,200	307,500	272,100
	48	456,100	342,300	304,200
	40	550,600	412,400	367,400
	32	666,200	491,300	435,300

The general impact on the annual total cost estimates of varying the amount of wastewater which is applied to a particular area of land is examined first. The amount of wastewater applied to a particular area is determined by two factors: (*a*) the weekly rate at which wastewater is applied and (*b*) the number of weeks of wastewater irrigation. The effect of varying these two variables is illustrated in table 2. For example, for reed canarygrass increasing the application rate from one to two inches a week with year-round (fifty-two weeks) wastewater irrigation reduces annual total costs from $347,300 to $274,000. Further increasing the application rate to three inches per week decreases the annual total costs to $249,100. Increasing the rate at which the wastewater is applied to the land effectively reduces the area which must be irrigated. Acreage requirements fall from approximately 301 to 159 to 111 acres for the application rates examined—one, two, and three inches per week, respectively. The longer the irrigation season, the lower the costs are also. For example, for the two-inch per week application rate with reed canarygrass, if the irrigation season is thirty-two weeks per year, annual total costs are $438,500, while for an irrigation season of forty-two weeks per year the annual total cost estimate is $369,700, and if the reed canarygrass can be irrigated year-round, annual total costs fall to $274,000. Thus, it may be concluded that the more wastewater which can be applied to a particular area of land without exceeding the capacity of the soil-crop combination to remove nutrients from the water, the lower annual total costs will be. Increasing the length of the irrigation season reduces effective land requirements from 294 acres for a thirty-two-week irrigation season to 159 acres for the year-round irrigation season.

Irrigation of crops such as alfalfa and corn cannot be carried out year-round and still maintain adequate renovation of the wastewater (Kardos et al.). If the irrigation season is restricted because of climatic constraints or other conditions associated with the winter season, the irrigation of corn and alfalfa become more cost-effective than irrigation of reed canarygrass (table 2). When irrigated with comparable quantities of water, say two inches per week for thirty-two weeks per year, alfalfa and corn are less costly than irrigation of reed canarygrass ($406,200, $423,700, and $438,500, respectively). In many areas reed canarygrass may be capable of being irrigated for a longer period of time than either alfalfa or corn as shown by Bradley. If, for example, reed canarygrass can be irrigated for forty weeks per year while corn and/or alfalfa can only be irrigated for thirty-two weeks per year, the reed canarygrass remains the least-cost alternative. If, on the other hand, alfalfa and corn can be irrigated for thirty-six weeks per year, the relative cost

advantage for irrigation of reed canarygrass for forty weeks annually decreases.

A fourth "crop" which may be irrigated with wastewater is forest land. Forests may be irrigated for longer seasons because of the coverage of the trees which permits infiltration of the wastewater in the soil during colder times. A disadvantage of forests is that a crop is seldom harvested because of the long time required for forests to mature. Thus, fewer nutrients are harvested from the land application site, which may lead to a lower performance in terms of nutrient removal. Revenues from the more frequent crop sales are higher for agricultural crops than for forests. Also, forest irrigation is more costly than irrigation of field crops because SSI must be used and the irrigation risers must be closer together to achieve an adequate distribution of the wastewater over the site (Pound, Crites, Griffès). If forests can be irrigated for longer periods of time, their cost effectiveness increases. An additional benefit to forest irrigation not quantified into the cost estimates is that forest irrigation may be more acceptable to the public than crop irrigation. Irrigation of forests is less visible and therefore less likely to lead to public opposition. One alternative for forest irrigation not examined in this analysis is the irrigation of fast-growing pulpwoods that can be harvested on four to five-year rotations. It is likely that this type of system would increase the renovative ability of a forest and also provide additional revenue to offset the costs of the irrigation operation.

A critical assumption underlying the analysis thus far is the value of reed canarygrass silage, assumed to be $15 per ton. This may not be a representative value for two reasons: (*a*) regional variations in silage values and (*b*) the lack of actual market price data underlying the estimate. In this analysis, the value of reed canarygrass silage is computed from its nutrient composition compared to corn and soybean oil meal and the price of the reference feeds (Bradley, pp. 92–93). Reducing the value of reed canarygrass silage decreases the relative cost effectiveness of the reed canarygrass option. For example, at $7.50 per ton for reed canarygrass silage (a 50% decrease) irrigation of reed canarygrass for forty weeks per year with a two-inch per week application rate costs $386,900. This value is about the same as irrigation of corn and alfalfa for thirty-six weeks per year at the two-inch per week application rate.

Minimizing Local Costs with a Construction Subsidy

Grants are available from the U.S. Environmental Protection Agency to pay for up to 75% of initial construction costs for conventional wastewater treatment facilities and up to 85% of initial construction costs for innovative and alternative treatment operations. Under the provisions of P.L. 95-217, land treatment is specifically defined as an alternative treatment technology. With a federal construction subsidy, a community may decide that it would be best to minimize local costs of LT as opposed to minimizing the total costs (local plus federal) of LT. If it does this, the community will discover quickly that irrigation of crops with shorter irrigation seasons, such as corn and alfalfa, may be more cost-effective (table 3). For example, with an 85% subsidy applied to eligible items and a two-inch per week application rate, irrigation of corn and alfalfa for thirty-two weeks per year compares favorably with irrigation of reed canarygrass for forty weeks per year. In fact, irrigation of alfalfa for thirty-two weeks per year is less costly than irrigation of reed canarygrass for forty-eight weeks per year. The subsidies provide an incentive for communities to select systems which are not necessarily the least-cost alternative from the viewpoint of society.

With a construction subsidy, maximizing the amount of wastewater applied is not always associated with minimization of local costs. When alfalfa and corn are irrigated with an 85% subsidy, local costs are lower with a two-inch per week application rate than for a three-inch application rate. This occurs because the additional crop revenue from irrigating more land offsets the additional unsubsidized costs for irrigation and land to the local community. With corn, an increase of four weeks in the length of the irrigation season for the one- and three-inch per week application rates does not reduce local costs sufficiently to be less costly than the two-inch per week alternative. For example, irrigating corn for thirty-two weeks per year at the two-inch per week application rate is less costly than irrigating corn at one or three inches per week

Table 3. Annual Local Cost Estimates (1978) for Alternative Cropping Patterns for a 1.0 mgd Solid-Set Irrigation System with an 85% Capital Subsidy

Crop	Weeks of Irrigation	Application Rate (inches/week) 1	2	3
		($)		
Reed canarygrass	52	116,400	103,300	98,600
	48	125,000	110,800	105,700
	40	141,900	124,700	118,900
	32	161,500	139,700	132,500
Alfalfa	40	105,300	98,900	101,700
	36	110,700	103,300	106,500
	32	115,800	107,400	111,000
Corn	40	120,600	112,800	120,900
	36	127,600	118,800	127,900
	32	134,900	124,800	134,900
	28	138,000	129,800	142,100
Forest	52	153,900	122,800	112,100
	48	165,500	131,900	120,200
	40	190,300	149,700	136,000
	32	221,800	170,400	153,600

for thirty-six weeks per year. Again, this phenomenon is caused by the additional crop revenue associated with irrigation at the two-inch application rate as opposed to the unsubsidized costs associated with the other irrigation alternatives.

Cost of Production: A Defensible Basis for Agricultural Price Supports?

E. C. Pasour, Jr.

Price supports have been used to increase the price of various agricultural commodities in the United States since the 1930s. Although price supports were conceived as a way of increasing farm income relative to nonfarm income, the level at which prices should be supported has been a key issue. Various farm organizations, economists, and politicians have maintained since the early 1920s that prices of farm commodities should be maintained at levels sufficient to cover production costs (Luttrell). The parity price concept was, in itself, an attempt to relate the support price to production costs through the prices-paid index. The shortcomings of the parity concept as a basis for setting agricultural prices are well known (Tomek and Robinson, p. 207).

Recently, cost of production has been proposed as a substitute for parity in measuring the equity of returns to agriculture. This concept is embraced in the Food and Agriculture Act of 1977 as a primary guide in determining support or target price levels. Producers and politicians largely have ignored a long tradition of attacks and debunking of cost of production as a welfare criterion. Economists have pointed out that there is no single cost of production number because cost varies (among other reasons) according to length of run and quantity of production (Stovall and Hoover). However, there appears to be no consensus even among economists that cost of production as a guide to setting support or target prices is, as recently stated, an "economically indefensible" concept (Johnson, p. 789). In a recent workshop devoted to evaluating Economics, Statistics, and Cooperatives Service (ESCS) cost-of-production work, for example, the focus was on "the difficulties of arriving at reasonable cost of production estimates" (p. i). This paper focuses on theoretical and measurement problems inherent in attempts to base price supports on cost and it questions whether "reasonable" cost-of-production estimates can be made for this purpose.

The analysis accepts the findings of other studies that government price and income support programs are capitalized into the price of land, rights to produce, and other assets (Hedrick; Seagraves). It does not discuss the rationale for income support of the farm sector or the effect of price supports on the stability of commodity prices; it is instead addressed to problems inherent in attempts to base support prices on production costs. The problems of using market prices of resources to estimate production costs when resources are specialized are explored both at the industry and firm levels. Measurement problems inherent in the concept of opportunity costs also are stressed. The analysis concludes that the use of cost data as a basis for agricultural price supports is "economically indefensible" regardless of whether cost estimates are made at the firm or industry level.

Specialized Resources

The use of cost of production as a basis for setting support prices presumes that opportunity cost is an objective concept which can, at least in principle, be measured by outside observers.[1] The use of market data has been suggested as a way of determining the cost of land and other inputs (Sharples and Krenz, p. 64). However, an intractable problem arises when one attempts to determine cost of production from market data when production involves specialized resources.

In the treatment of cost, economic theory texts generally assume a world of unspecialized resources (Leftwich, Ch. 9). In this model, cost can be defined independently of product demand, so that a change in demand has no effect on production costs. In the real world, however, land, labor, productive facilities, and entrepreneurship are specialized to the firm in the sense that it is impossible to duplicate precisely the resources of any particular firm (Friedman, p. 147).[2] Friedman points out the problem posed by specialized resources to conventional cost (and, hence, supply) analysis.

> The existence of specialized resources . . . makes it impossible to define the average cost of a particular firm for different hypothetical outputs independently of demand. . . . Take the copper mine of the preceding paragraph: its cost curve cannot be computed

E. C. Pasour, Jr. is a professor in the Department of Economics and Business at North Carolina State University.

This is paper No. 6147 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh.

The author wishes to thank Marc Johnson, C. R. Pugh, and M. K. Wohlgenant.

[1] In this and the following section of this paper, "cost" is taken to be equivalent to the market outlays of conventional static equilibrium.

[2] A specialized input at the industry level is sometimes referred to as a "specific input," i.e., one whose supply curve is less than perfectly elastic.

> without knowledge of the royalty or rent that must be paid to owners of the mine, if the firm does not itself own it, or imputed as royalty or rent, if the firm does. But the royalty is clearly dependent on the price at which copper sells on the market and is determined in such a way as to make average cost tend to equal price . . . . The equality of price to average cost . . . is forced on the firm by the operation of the capital market or the market determining rents for specialized resources. (Friedman, p. 147)

If firm A owns a superior input (e.g., land which is unusually productive), the return to the specialized resource is capitalized into higher land costs. Competition bids up the price so that firm A faces costs similar to those of firm B and other firms with less productive resources when the returns to specialized resources are included in costs.

Under these conditions, average cost of production cannot be defined independently of demand conditions; an increase in product demand which increases expected product price increases returns to specialized resources and, consequently, costs. The larger the increase in expected product price, the higher the returns to specialized factors. Competition results in a capitalization of the returns to the specialized factors into higher costs so that higher rates of return on investment to firms with the more productive factors are not expected to persist over time.

Similarly, when production of an agricultural product is restricted as a means of supporting price above the market level, the right to produce (tobacco poundage quota, peanut allotment, milk base, etc.) acquires a value. The value of the right to produce, as in the case of other resources not perfectly elastic in supply, cannot be determined independently of product demand. Thus, an increase in product price will increase the expected value of the right to produce and, consequently, the expected cost of production.

When expected product price is supported above the current market level, increases in product price will be capitalized into prices of production rights, land, and other specialized inputs through competitive market forces so that expected product outlays tend to rise to meet expected returns. Consequently, attempts to set price supports on the basis of production outlays are futile in real world production because the higher the level at which prices are supported above the market level, the higher will be the required production outlay. As long as some inputs are less than perfectly elastic in supply, there is no way to avoid this dog-chasing-its-tail ratchet effect in which an increase in the level of price support brings about an increase in production outlays.

The preceding analysis also casts light on land cost. Some economists have held that land costs should be excluded from production costs which are to be used as a basis for setting support prices. The costs of land, however, are a part of the individual producer's opportunity cost. Any decision to exclude portions of cost in arriving at "production cost" must be arbitrary. There is no more reason to exclude the cost of land than to exclude the cost of a production right (e.g., allotment cost). In each case, the outlays represents a bona fide cost from the standpoint of the individual producer.

Implications for Cost Measurement

Consider the procedure for estimating cost commonly used in constructing enterprise budgets in which the market price of each resource used in producing a product is taken as an estimate of that input's cost. The cost of producing peanuts, for example, is determined by adding together the market value (or estimates thereof) of land, allotment value, labor, fertilizer, pesticides, machinery, and other inputs required to produce an acre of peanuts. Market outlays are equal to opportunity costs, however, only when resources are unspecialized under highly restrictive equilibrium conditions (Vaughn, p. 714).[3]

When resources are specialized and producers are motivated only by pecuniary considerations, competition in the capital market forces average cost toward an equality with price: hence, average costs for different firms will tend to be equal provided they are all properly computed so as to include the quasi-rents (returns to specialized resources). Under these conditions, a difference between expected product price and the sum of market input prices may be taken as an indication of the efficiency of the capital market in revaluing assets (Friedman, p. 148). Thus, the use of market input prices to estimate production cost is theoretically unsound in a world of specialized resources including production rights and land.

Although market prices of fertilizer, pesticides, and other nonspecialized inputs generally are used in enterprise budgets, the concept of market price often has little meaning in the case of operator labor, management, land, and capital facilities.[4] The characteristics and value of these specialized inputs is acknowledged to vary from firm to firm. Consequently, a great deal of effort has been devoted to production cost analyses at the firm level.

[3] "If the whole economy is not operating at full competitive equilibrium, profits-losses may occur and, hence, observed outlays cannot be taken to reflect foregone opportunities of the actual decision-makers in any general setting. . . . . It is important to note that quasi-rents cannot exist in the competitive equilibrium required in this model. . . . The reason is that the presence of 'quasi-rents,' the individual or the firm has available more than one loss-avoiding alternative course of action. . . . even in full equilibrium resource-service prices reflect costs only if nonpecuniary advantages or disadvantages are absent from the choices of resource-supply agents" (Buchanan 1969a, pp. 49–75, and 86).

[4] Coase (pp. 110–13) cautions, however, that even in the case of purchased inputs the price paid by the firm is unlikely to equal their opportunity cost.

Estimating Cost at Firm Level

Estimation of cost at the firm level, however, is no panacea. There are at least three kinds of problems. The first two kinds of problems pertain to the procedure of equating opportunity cost with market outlays. First, the problem posed by specialized resources discussed above is not obviated by estimating cost at the firm level. Typically, cost studies based on accounting data reveal wide differences in average cost from firm to firm. Data obtained through the North Carolina Dairy Farm Business Records Program, for example, show that the net cost of producing milk by the enrolled dairymen was twice as high for the upper 10% when compared with the lower 10% of farms ranked according to cost of production (Wells and Sutter). The variation in accounting costs between firms, however, need not be caused by differences in *ex ante* costs but may represent differences in the accuracy of accounting data or in the efficiency of the capital market in revaluing resources. Competition in the capital market will force expected outlays at the firm level toward expected product price in the manner described above.

Second, quasi-rents cannot exist in competitive equilibrium if market input prices are to represent opportunity costs. If there are no rents and nonpecuniary considerations do not enter the choices of resource supplying agents, the opportunity costs are the objectively measurable outlays of competitive equilibrium. If such rents exist, however, "there can be no presumption that anticipated outlay measures subjective opportunity costs, those that must influence actual choice behavior" (Buchanan 1969a, p. 75). Thus, the existence of specialized resources (and the consequent quasi-rents) destroys the link between market prices and choice-influencing costs.

Third, and closely related, estimation problems arise because of the subjective nature of opportunity cost. The opportunity cost of any decision is the value of sacrificed alternatives as a result of the action taken. Thus, cost as it influences entrepreneurial choice is the decision maker's own assessment of opportunities foregone. Furthermore, because the opportunities foregone are not actually experienced, the assessment of the rejected course of action depends upon the decision maker's anticipations of future conditions. In empirical work, the expected value of the sacrificed alternative tends to be ignored in estimating cost and is replaced by factor prices. Cost defined as resource outlay, however, has no necessary connection with the value of the rejected course of action or, consequently, the entrepreneur's act of choice (Thirlby).

Note how the concept of cost implicit in the following passage is unrelated to the act of choice and inconsistent with the opportunity cost concept.

> Costs per unit vary among farms for many reasons. First, a farmer's actual production usually does not equal his expected production . . . . For example, the 1974 corn yield of 74.3 bushels per acre was unusually low. With normal weather conditions, the yield would have been 20–25 percent higher, and costs per bushel, much lower. If farmers had obtained 1973 corn yields in 1974, their costs would have been reduced over 20 percent per bushel. (Sharples and Krenz, p. 65)

Cost in the choice-influencing opportunity cost sense, however, concerns sacrificed alternatives at the moment of choice. Whether the yield is eventually higher or lower than anticipated has no relevance to opportunity cost. The opportunity cost is not affected unless the decision maker's estimate of the best alternative is affected at the time the decision was made (Alchian, p. 303).

The following example demonstrates why cost as it influences entrepreneurial choice varies widely from producer to producer and illustrates the problems faced by the outside observer in measuring opportunity cost. Consider the cost of land in the production of corn. The cost of similar land in corn may be quite different for Jones relative to his neighbor Smith. The opportunity cost of land used to produce corn is the value of that land in its best alternative use (say soybeans). Costs occur in the planning stage and any planning acitivity must deal with an uncertain future. Consequently, the expected value of land used to produce soybeans hinges on expected soybean outlays, prices, and yields. Jones, for example, may anticipate a return to land of $25 per acre when using the land in soybeans. Smith, on the other hand, being more optimistic about future soybean yields and prices, may anticipate a return of $40 per acre to land in soybeans. Under these anticipated conditions, the opportunity cost per acre of land to produce corn is $25 for Jones and $40 for Smith. These are the relevant costs for Jones and Smith to impute to land in producing corn when the land is owned; these are also the relevant costs even though both farmers may have paid the same market or contract rental price for land. Long-term contracts at a fixed price do not prevent fluctuations in opportunity cost.

Uncertainty also complicates the estimation of overhead costs. The relevant depreciation (including obsolescence) cost hinges on the unknown future and, consequently, expectations are crucial in the estimation of overhead costs of machinery and other capital.[5] Depreciation and interest cost estimates by outside observers must be based on the historical "cost" records of the business firm or on the observer's expectations of future conditions. Because the relevant cost estimates are necessarily expectations rooted in uncertainty, overhead cost estimates by outside observers may bear little rela-

[5] "In no sense can costs during any period be said to depend solely on prices during that period. . . in fact, almost every real world decision concerning how to produce depends at least in part on the views held about the future" (Hayek, p. 198).

tionship to the opportunity costs which motivate the entrepreneur (Shackle 1972, 1974).

Finally, subjectivity enters cost estimates when Jones places a value on his time. The appropriate cost of time for Jones in producing corn is the opportunity cost of his time. This value of the best sacrificed alternatives as it affects choice, however, is unique depending upon the decision makers subjective evaluation, and is not observable to the independent analyst.[6]

These examples demonstrate that the cost of land, labor, and capital inputs (as they influence entrepreneurial choice) are inherently subjective under real world conditions and not observable by outside parties (Pasour). A recognition of this phenomenon explains why Jones may rationally choose to plant corn and Smith to plant soybeans even though a conventional enterprise budget of costs and returns of corn production might show the same cost for each producer.

How can there be ambiguity over the seemingly simple opportunity cost concept? At least some of the confusion follows from the usual textbook treatment of cost. Major emphasis is placed on profit maximization when costs and returns are assumed given or known to economic actors and observers (Kirzner 1973, 1978). Under real world conditions of uncertainty, however, these data are not given and a key role of the entrepreneur is to assess the cost of alternative courses of action. Moreover, there is no reason to expect a cost estimate by an entrepreneur to correspond to that of the economist because the data upon which choices are based are distinct from data that can be objectively measured by external observers (Buchanan 1969b, p. 64).

This paper has discussed problems related to defining and measuring cost used as a basis for price supports. The cost of producing a commodity is meaningful only in a static equilibrium model and, even then, cost cannot be defined independently of demand when resources are specialized. Under real world conditions, opportunity costs are subjective and vary widely between producers. The preceding analysis does not deny that government can vary output levels by price setting. What is challenged is the contention that such an approach involves the basing of price supports on cost. In view of the problems raised above, attempts to define and estimate "reasonable cost estimates" as a basis for agricultural price supports appear to be foredoomed.

[Received June 1979; revision accepted October 1979.]

[6] Even in full market equilibrium where all resources are unspecialized, the choice influencing cost of the resource units is not observable in money prices paid for resources if nonpecuniary considerations are present in decisions made by suppliers of labor (or other resources) (Buchanan 1969a, p. 86–87).

A Critique of Exchange Rate Treatment in Agricultural Trade Models: Comment

Thomas Grennes, Paul R. Johnson, and Marie Thursby

In a recent article in this *Journal*, Chambers and Just criticize partial equilibrium models of trade which attempt to show the effect of currency devaluation on domestic prices. Three of their main points are (*a*) cross-price effects cannot be ignored, (*b*) the response of domestic prices to exchange rate disturbances may (but need not) be different from their response to foreign price disturbances, and (*c*) demand systems derived from weakly separable utility functions may be useful in constructing trade models. We read the Chambers-Just note with ambivalence because we have made all of these points ourselves, but surprisingly our 1977 paper was accused of advocating a contrary position. In addition to clarifying the misrepresentation of our work, we offer a comment on the authors' claim that there are neither theoretical nor empirical reasons for domestic prices to rise by no more than the rate of devaluation.

Concerning cross-price effects, any study of the effect of dollar devaluation on the demand for U.S. wheat cannot ignore the prices of other kinds of wheat and the prices of substitute grains. The distinguishing feature of our model which Chambers-Just describe as assuming zero cross-price elasticities (p. 251, 254), is that demanders distinguish wheat by country of origin. That cross-price effects are explicitly incorporated should be apparent from the following system of demand equations, but evidently it was not:[1]

$$Q_{ij} = f(P_{ij}^{D}, Z_i) \qquad i, j = 1, \ldots, n,$$

where the i subscript refers to the country importing wheat, and j refers to the country that is exporting wheat, and Z_i refers to exogenous demand shifters such as income and prices of substitute grain in the ith importing country. This system incorporates two kinds of cross-price effects: (*a*) $n - 1$ cross-price elasticities with respect to wheat supplied by countries other than j, and (*b*) cross-price elasticities with respect to other grains which enter through the Z_i's. For example, the demand for U.S. wheat in Japan depends on the price of U.S. wheat in Japan, the price of Canadian wheat in Japan, the price of Australian wheat in Japan, etc. Thus, the wheat prices are determined by a general equilibrium system, so that any disturbance that affects one of these substitutes also affects all the others.[2] In addition, we entered as an exogenous variable the price of corn. This class of models has some shortcomings, but failure to incorporate prices of related products is not one of them. Thus the contention of zero cross-price effects is gratuitous.

A possible shortcoming of our model is that wheat supply and prices of substitute grains are exogenous variables, but whether the benefits of a larger model are worth the costs in terms of additional complexity is a question without an easy answer. Even a model in which wheat supply and prices of other grains appear as endogenous variables is not fully general, because it ignores the feedback from grain prices to the exchange rate, substitution between grain and a broader class of goods, and substitution between goods, bonds, and money.[3] While there is some merit to the suggestion that trade models should incorporate a broader range of products, there is no logical end to this process until all domestic and foreign markets are included. Thus, Chambers-Just are vulnerable to the same Walrasian criticism that they make; i.e., some potentially important endogenous variables are omitted.

Domestic prices may not respond in the same way to exchange rate changes as they do to changes in foreign prices. Our wheat model takes this possibility into account by treating wheat as a differentiated product. U.S., Canadian, and Australian wheat are all substitutes, so that a disturbance such

Thomas Grennes is an associate professor and Paul R. Johnson, a professor of economics and business, North Carolina State University; Marie Thursby is an assistant professor of economics, Ohio State University.

[1] After listing the own price elasticities for the various wheats, we stated that "From these basic elasticities, all the direct and cross-price elasticities can be derived." (Johnson, Grennes, Thursby, p. 629). On the same page we mentioned that "The major exogenous variables are demand shifters (income, price of substitute grain, imports by ROW). . . ." Another explicit statement is "Looking down that column, one can see the large changes are from a change in demand such as income or competing prices. . . ." (Johnson, Grennes, Thursby, p. 627).

[2] While our model does not assume zero cross-price elasticities, it is partial equilibrium in the sense that prices of substitute grains are exogenous variables. For example, a devaluation will affect prices of the n-types of wheat, and these cross-price effects are included in the model. However, the effect of devaluation on the supply and demand for corn is not endogenous and would enter through Z_i.

[3] In more general models there are both theoretical and empirical reasons to expect domestic prices to rise by no more than the rate of devaluation. On theoretical issues see Kemp chap. 14. On empirical work see the surveys done at the Federal Reserve by Lowrey-Hooper and Prakken. For an attempt to incorporate the money supply in analyzing agricultural markets see Shei and Thompson.

as a devaluation of the U.S. dollar will increase all their prices, but because they are imperfect substitutes, the prices will rise by different amounts. Also a 10% devaluation of the Canadian dollar will have a different effect on wheat prices than a 10% devaluation of the U.S. dollar. Thus we were surprised to read that our model requires that exchange rates and foreign prices have the same effect on domestic prices. The only restriction we have imposed on exchange rates is that only changes in the real exchange rate (the money exchange rate relative to the general price level) alter exports. Thus, the demand for U.S. wheat exports should be unaffected by a simultaneous increase of 10% in the dollar price of all foreign currencies and a 10% increase in all U.S. product prices, including wheat. As a theoretical matter our model permits a differential response to exchange rates and foreign prices, but the issue is ultimately an empirical one. Richardson has recently presented evidence which is contrary to the hypothesis of differential response. He regressed the Canadian price on the U.S. price and the exchange rate for twenty-two disaggregated products. He carefully held constant inflation, transport costs, and other shifters. In only three of twenty-two cases could he reject the hypothesis that the response to price was the same as the response to the exchange rate.

Chambers-Just propose to improve model specification by assuming a separable utility function in order to permit a two-state budgeting process by consumers. We can hardly disagree with this suggestion because it is a separable utility function permitting two-stage budgeting which underlies the demand side of our model.[4] Our exposition may not be perfectly lucid, but the following statement from our 1977 paper indicates that we have employed the notion of separability and found it to be useful in trade models. "His model, and our variant, can be derived by formally maximizing an underlying utility function in a two-stage process." (Grennes, Johnson, Thursby, p. 626). Paul Armington applied the idea to trade models a decade ago, and we have adapted a version of his model to grain trade. Collins and Wells also have employed demand systems based on separable utility to study trade in wheat and feed grains.

Chambers-Just deny that there are theoretical reasons to expect prices to rise by no more than the devaluation. At the same time they accept the so-called law of one price, which states that the domestic currency price (p) of a traded good will equal the domestic currency equivalent price ($e\gamma$) of the same product abroad, where e is the price of domestic currency in terms of foreign currency, and γ is the foreign currency price of the traded product. This can be expressed in terms of rates of change as

$$\frac{dp}{p} = \frac{d\gamma}{\gamma} - \frac{de}{e}.$$

By definition of a devaluation of the domestic currency $\frac{de}{e}$ is negative, and for a small country exporter $\left(\frac{d\gamma}{\gamma} = 0\right)$, domestic prices rise by the full amount of the devaluation, $\frac{dp}{p} = -\frac{de}{e}$. In the large country case, which is more appropriate for U.S. agricultural exports, the domestic price rises by less than the devaluation $\left(\frac{dp}{p} < \frac{de}{e}\right.$ in absolute value), provided that foreign currency prices fall $\left(\frac{d\gamma}{\gamma} < 0\right)$ as devaluation induces a larger volume of exports. This result is well known, and it is the basis of the common concern of policy makers that devaluation will worsen a country's terms of trade on the export side (see Robinson, chap. 1). As long as one invokes the law of one price, the domestic price will rise by more than the devaluation only if the foreign price rises. Somehow devaluation must improve the terms of trade on the export side. This is a curious condition because it is generally agreed that devaluation increases the volume of exports if not the value. If dollar devaluation causes Americans to export more bushels of wheat, how does this bring about an increase in the foreign wheat price? There may be good reasons for abandoning the law of one price (see Isard, Grennes, Johnson, Thursby 1978b) but Chambers-Just do not address that issue. Thus, there is a theoretical reason to expect domestic prices to rise by no more than the devaluation.

Whether domestic prices rise by more than devaluation is ultimately an empirical question, and work remains to be done. However, there is some relevant evidence that was overlooked by Chambers-Just. In a paper by Yandle which appeared in the same volume as one by Clark (which they cite), there is evidence on the effects of the dollar devaluation of 1971–74 on domestic wheat prices. The dollar fluctuated during the period and it depreciated by different amounts against different countries, but on the average his results are consistent with the proposition that a dollar devaluation by $X\%$ raised domestic wheat prices by no more than $X\%$.

A recent paper by Kreinin presented similar results on the responsiveness of domestic prices to currency changes. He estimated the effects of the 1970–72 currency realignments on prices of aggregate exports and imports of eight countries, including the United States. He also estimated the effect

[4] Whereas CJ suggest a weakly separable function, we assume a Pearce separable function which yields a more manageable parameter space than weak separability. See Johnson, Grennes, and Thursby (1979) for a discussion of the implications of this function.

of dollar devaluation on prices of certain disaggregated manufactured exports (SITC categories 5–8). His main result is that exporters "passed-through" nearly all of the effects of devaluation to foreign consumers in the form of lower prices. Foreign currency prices fell by 85%–100% of the devaluation, so that domestic prices rose by no more than 15%. Similar results were obtained for the disaggregated U.S. data.

We concluded that a devaluation of 10% raised wheat prices by 7%. Chambers-Just interpreted this as meaning that "devaluation had relatively little impact on the agricultural sector of the economy" (p. 249), and they contrasted our results with the 1974 paper of Schuh which they described as finding that "devaluations have been an important determinant of agricultural exports and have led, in part, to the high domestic prices of the early 1970s" (p. 249). A 7% increase in prices is not a negligible effect relative to many disturbances in the agricultural sector. Obviously whether devaluation is important or not depends on what it is compared with, and in the 1973–74 period dollar devaluation had a smaller effect on U.S. wheat prices than insulating trade policies of foreign governments which shifted demand on to U.S. wheat. On the issue of the importance of devaluation, we see no conflict between our results and Schuh's. His 1974 paper was important in that he directed attention to the relationship between exchange rates and agricultural prices, but he presented no empirical evidence on the subject.[5] In a subsequent discussion of some trade elasticities of Tweeten's, he offered the judgment that domestic agricultural prices would rise by 77% of the dollar devaluation.[6] This is so close to our figure of 70% that we deny the assertion by Chambers-Just that there is a conflict. The critique of the theoretical and empirical literature presented by Chambers-Just is incomplete and misleading. We cannot object to their empirical work on exchange rates and prices since they present none.

[5] In his reply to a comment by Vellianitis-Fidas on his 1974 paper, Schuh stated, "To the charge that I offered little evidence (which appears to mean empirical evidence) in support of my central hypothesis, I plead guilty. My paper was an exercise in analysis and an appeal to the logic of the situation. An important goal, in fact, was to suggest hypotheses which might help us better understand our own economic history" (1975, p. 696).

[6] "If the 13% devaluation constitutes an equilibrium, the increase in the relative price of agricultural products after adjustments have worked themselves out may be something on the order of 10%. That is no small amount for a change in the internal terms of trade, however" (Schuh 1975, p. 699).

A Critique of Exchange Rate Treatment in Agricultural Trade Models: Comment

Michael R. Reed

In the May 1979 issue of the *Journal*, Chambers and Just (CJ) critically reviewed theoretical and empirical work on the role of exchange rates in agricultural prices and trade. CJ contend that the assumption of zero cross-price elasticities between commodities leads to an inaccurate portrayal of import demand and export supply functions and therefore an inaccurate portrayal of the effects of exchange rate changes on trade.[1] This author agrees with that contention. Incorporation of possible cross-price effects will clarify the effect of all variables in the system. However, this author feels that the remedy CJ have proposed for incorporating these cross-price effects in order to analyze the effect of exchange rate fluctuations is less than desirable. The proposition will be put forth that the inclusion of prices for commodities which are close substitutes (complements) to the good studied and an index of all domestic prices in the country studied is more sound in theory and practice than the cure proposed by CJ.

CJ argue that "a separate exchange rate variable (involving a weighted price index of other traded goods if feasible)" (p. 256), should be included in the equation for an excess demand function. This separate exchange rate variable would serve as a price index for all other traded goods. The structure under which this suggestion is derived is unclear. The exchange rate, in and of itself, is only relevant to excess demand as a deflator. It is a way of transforming prices into a currency which is relevant to producers and purchasers of goods in the country. Japanese producers and purchasers are interested in the yen price, not the dollar price. Therefore the idea of including the exchange rate as a separate regressor for an excess demand function is structurally unsound.

If the exchange rate is multiplied by a weighted price index of other traded goods, other problems develop. The first problem is that the "purchasing power parity theory" may not hold. Exchange rates may not reflect the purchasing power of the currencies involved. Therefore the exchange rate multiplied by a weighted price index of other traded goods does not accurately reflect the domestic currency price of goods in the country.

Second, there is the problem of price transmission for traded goods in a world where trade barriers are common. A change in the export price of a commodity may not be completely reflected in the internal price of the commodity in an importing country.

Finally, the exchange rate change also can have indirect effects on all goods in the economy. The exchange rate directly affects traded goods, but because of cross-price effects the price of nontraded goods also could change. These price movements for nontraded goods could then influence the excess demand function for the country. These cross-price effects between traded and nontraded goods are important, but certainly outside the scope of an empirical agricultural trade model.

A way of circumventing the problems of cross-price effects on nontraded goods and price transmission for traded goods is to include an index of domestic prices in the excess demand function. The structure of the relationships between exchange rates and domestic prices is not estimated, so the full effect of an exchange rate fluctuation would not be determined. However, the structure does allow all other domestic prices in the country to influence the excess demand for the commodity. Domestic price indices are available for most countries (International Monetary Fund).

Each commodity judged to have a relatively important cross-price elasticity can be included in the excess demand function. For example, the price of corn presumably would be included in the export supply function for wheat by the United States. Assuming no trade barriers or transportation costs, the internal price for a good (γ_j) is the world price for the good (P_j) multiplied by the exchange rate between the currency in which the world price is denominated and the currency of the country in question (e),

$$(1) \qquad \gamma_j = P_j e.$$

$P_j e$ would be included for own-price effects and for cross-price effects of commodities judged to be close substitutes (complements). In this way, first

Michael R. Reed is an assistant professor in the Department of Agricultural Economics at the University of Kentucky.

The author wishes to acknowledge Professor Maury E. Bredahl, University of Missouri, for his helpful comments.

[1] Throughout the remainder of this paper the term excess demand will be used rather than import demand and/or export supply. If the world price is relatively high, the excess demand function will be an export supply function. If the world price is relatively low, the excess demand function will be an import demand function.

round effects of an exchange rate change for commodities that are close substitutes (complements) are embodied in the excess demand function. If the "purchasing power parity theorem" does not hold, the approach suggested by Bjarnson, McGarry, and Schmitz may be used. Instead of using yearly observations of the exchange rate, use a base period exchange rate for all observations.

Fletcher, Just, and Schmitz inserted the exchange rate as a separate regressor in their export demand model for North American wheat. CJ agree with this specification "in the case where all other individual price movements are unimportant" (p. 255). The rationale for this specification is that even when the world price and the exchange rate are the only factors influencing excess demand, there is no reason to restrict exchange rate changes to have the same impact as changes in the world price. This is only partially true. In the short run, an exchange rate change may be viewed as a more permanent development than a change in the world price. This may be true in a regime of fixed exchange rates, as was the case prior to 1971. An exchange rate change is less likely to be reversed than a change in the world price. Therefore, adjustment to an exchange rate change may be more rapid than an equal change in the world price. This situation is much less likely when exchange rates are floating, as they are now.

In the long run there is no intrinsic difference between exchange rate variations and world price variations of equal magnitude, even under a system of fixed exchange rates. There is no uncertainty as to the permanence of either price fluctuation. All adjustments in excess demand brought about by an exchange rate change may be completed after one year, while the adjustments may take longer for a change in the world price. However, after all adjustments have taken place, the impact of an exchange rate change is identical to a world price change of the same magnitude. In order to embody differential response lags for exchange rate and world price changes, a distributed lag framework is appropriate. The exchange rate and the world price of the commodity are included as separate regressors with a constraint that the sum of the weights for coefficients on the two regressors be equal. This allows a difference between short-run impacts of exchange rate and world price movements, but incorporates the postulate that the long-run impacts are identical. Wilson and Takacs used this technique to explain aggregate trade by several industrial countries. Their findings suggest that there are differential response lags for exchange rate and world price changes under a regime of fixed exchange rates.

With respect to agricultural trade models, lagged exchange rates and world prices may be linked to excess demand through the supply side. Supply of most agricultural commodities is influenced by lagged prices. Whether there is a differential response between exchange rate changes and world price changes because of uncertainty as to the permanence of the change for agricultural products is a matter for future empirical research.

Cross-price effects should be incorporated into theoretical and empirical models of agricultural trade, as CJ argued. But the structural excess demand relationship should not be distorted in order to capture the full effect of a change in the exchange rate. Exchange rate movements have far-reaching impacts on the entire economy of a country. Agricultural economists must either model the entire economy of the country or countries in question, or settle for estimates of partial effects of exchange rate changes.

A Critique of Exchange Rate Treatment in Agricultural Trade Models: Reply

Robert G. Chambers and Richard E. Just

We would like to correct the seemingly substantive points made by Grennes, Johnson, and Thursby (GJT). One of the three main points they claim we make is misrepresented. We did not claim that their "model requires that exchange rates and foreign prices have the same effect on domestic prices." What we question is whether or not it is appropriate to force the exporter price of grains and exchange rate changes "to have the same relative effect on excess demand in the importing country" (Chambers and Just, p. 254).

Clearly from our discussion, we are questioning the applicability of "the assumption of zero cross-price elasticities between the traded agricultural commodity and all other goods for which prices are not constant or . . . other similarly restrictive assumptions," such as considering only corn cross-price elasticities (p. 251). In the Johnson, Grennes, and Thursby (JGT) model, for example, a certain percentage of change in, say, the Japanese price of U.S. currency and an equal percentage of change in the U.S. price of wheat (and corn if it is considered endogenously) has the same effect on Japanese demand for U.S. wheat (given JGT's assumptions). This is generally true only if wheat (and corn) is (are) the only commodity(ies) traded between the United States and Japan. But in 1976, for example, trade in all cereal grains amounted to only 15.5% of U.S. exports to Japan (United Nations). As clarified below, a change in the exchange rate can have more far-reaching effects than a change in U.S. grain prices because of implications for trade in all other goods and the related impacts on balance of trade and, in turn, the Japanese purchasing power for U.S. wheat.

The major part of GJT's other comments relate to the use of separability theory in demand specification and whether cross-price effects are adequately considered. On these points, we reply emphatically that they restrict many cross-price effects to be zero, and that their model (as they have described it in JGT does not include the essential generality afforded by separability. To explain these points, we will first review the concept of separability and Armington's application of it as a backdrop for our discussion. Consider a utility function $U = U(Q_{11}, Q_{12}, \ldots, Q_{1m}, Q_{21}, \ldots, Q_{n1}, \ldots, Q_{nm})$ where Q_{ij} is good j of commodity group i. Where Q_{ij} has price P_{ij} and m represents total income, the associated maximization problem is to maximize U subject to $\sum_{i=1}^{n} \sum_{j=1}^{m} P_{ij} Q_{ij} = m$. The theory of separability implies, under certain conditions (see Blackorby, Primont, Russell), that this consumer maximization problem can be broken into two stages such that income is first allocated to groups of commodities and then within the groups of commodities. The first-stage problem is to maximize $U^* = U(Q_1, Q_2, \ldots, Q_n)$ subject to $\sum_{i=1}^{n} P_i Q_i = m$ where P_i is a price index and Q_i is a quantity index for group i. The resulting group demand equations may be written as

$$(1) \qquad Q_i = Q_i(P_1, \ldots, P_n, m).$$

Given this allocation and expenditure, m_i,

$$(2) \qquad m_i = P_i \cdot Q_i(P_1, \ldots, P_n, m),$$

on group i, the within-group allocation problem is to maximize $U^i = U^i(Q_{i1}, \ldots, Q_{im})$ subject to $\sum_{j=1}^{m} P_{ij} Q_{ij} = m_i$. The resulting within-group demand equations may be written as

$$(3) \qquad Q_{ij} = Q_{ij}(P_{i1}, \ldots, P_{im}, m_i),$$

or, substituting (2) into (3), as

$$(4) \quad Q_{ij} = Q^*_{ij}(P_{i1}, \ldots, P_{im}, P_1, \ldots, P_{i-1}, P_{i+1}, \ldots, P_n, m).$$

In Armington's application of this framework, he specifies U^i as a constant-elasticity-of-substitution function,

$$U^i(Q_{i1}, \ldots, Q_{im}) = \left(\sum_{j=1}^{m} b_{ij} Q_{ij}^{-\rho_i} \right)^{-1/\rho_i},$$

from which one finds equation (3) to be of the form

$$(5) \qquad Q_{ij} = b_{ij}^{\sigma_i} m_i \cdot P_{ij}^{-\sigma_i} P_i^{\sigma_i - 1},$$

where $\sigma_i = 1/(1 + \rho_i)$. Or, finally, substituting (2) in (5) obtains the familiar forms used by Armington,

$$(6) \qquad Q_{ij} = b_{ij}^{\sigma_i} Q_i (P_{ij}/P_i)^{-\sigma_i}, \text{ or}$$

$$(7) \qquad \frac{Q_{ij}}{Q_i} = b_{ij}^{\sigma_i} \left(\frac{P_{ij}}{P_i} \right)^{-\sigma_i}$$

Robert G. Chambers is an assistant professor of agricultural and resource economics at the University of Maryland; Richard E. Just is professor of economics at Brigham Young University and professor of agricultural and resource economics at the University of California, Berkeley, on leave.

Scientific Article No. A2731, Contribution No. 5604 of the Maryland Agricultural Experiment Station.

which, of course, still basically correspond to equation (3).

Now return to JGT's claim that their model "can be derived by formally maximizing an underlying utility function in a two-stage process" (p. 626). Based on the description of the model in their earlier paper as well as in their comment, JGT postulate demand equations as

$$Q_{ij} = f(P_{ij}^D, Z_i),$$

"where Q_{ij} is quantity consumed in country i of wheat originating in country j, P_{ij}^D is consumer price in country i of wheat from country j, and Z_i is exogenous demand shifter for country i" (p. 621). In both their earlier paper and their comment, the exogenous demand shifters are identified as income and price of substitute grain. In addition, the earlier paper mentions imports by the rest of the world (which excludes their six endogenous countries). This specification is not a complete application of either Armington's model or separability. First of all, to follow the Armington specification, Q_{ij} must be specified following equation (6) as a function of an aggregate wheat quantity index for country i, the price in country i of wheat country j, and an aggregate wheat price index in country i; or following equation (5), as a function of country i total expenditures on wheat, m_i, along with the same two price variables; or following equation (7) with market shares, depending on relative prices. On the contrary, however, JGT do not specify Q_{ij} as a function of either total expenditure on wheat in country i or a total wheat quantity index in country i, and, although market shares are mentioned in their appendix (JGT), their equation (1) was not defined in terms of market shares or relative prices. Furthermore, the price of a substitute grain does not appear in Armington's equations (5), (6), or (7).

Because JGT have Q_{ij} as a function of income and a substitute grain price, their specification follows, instead, equation (4); but, in this context, the price indices of other groups are clearly omitted, and, hence, the associated cross-price elasticities are forced to zero. Corn is apparently the only other commodity besides wheat for which a cross-price is considered. Since the JGT demand function does not include all prices in the rest of the economy or variables such as m_i or Q_i which summarize the effects of prices in the rest of the economy, the JGT model (as it is described in JGT and GJT, this issue) ignores the possibility of substitution of wheat for all other commodities except corn as the prices of other commodity groups change. We did not claim that they consider no cross-price elasticities but rather that they do not consider the full impact of exchange rates that can enter through all cross-price elasticities (because many cross-price effects are not considered). Each of the other cross-price elasticities may be individually unimportant but the exchange rate can affect every cross-price (of traded goods) and the associated aggregate impact of all omitted cross-price elasticities may be significant.

Perhaps the confusion arises from GJT's peculiar notion of general equilibrium. They claim that, in their model, "the demand for U.S. wheat in Japan depends on the price of U.S. wheat in Japan, the price of Canadian wheat in Japan, the price of Australian wheat in Japan, etc. Thus, the wheat prices are determined by a general equilibrium system, so that any disturbance that affects one of these substitutes also affects all the others. In addition we entered as an exogenous variable the price of corn" (p. 249). We fail to understand how this system can be a general equilibrium system if the price of corn is exogenous. And what about all other commodities traded by, say, Japan? A change in the exchange rate affects all other traded commodities; hence, the balance of trade and associated purchasing power by Japan for wheat abroad can be affected much more extensively than if only wheat trade is considered.

Our critics acknowledge, in a footnote to their general equilibrium claim, that "the effect of devaluation on the supply and demand for corn is not endogenous and would enter through Z_i" (p. 249). But two further problems must be considered in this context. First, how can the effects of exchange rates on trade in other commodities and the related impacts on wheat trade enter their model when exchange rate effects are tied specifically to price effects, and wheat and corn prices are the only commodity prices included? Second, if corn prices are considered exogenously, then how can even the adjustment of corn price to exchange rate changes be considered in the kind of impact analysis reported by JGT (p. 622)? Corn prices would not simply adjust proportionally to exchange rates when the laws of supply and demand are at work; so without further information the effects would be unclear. Thus, based on the description of their model (JGT), it appears that the JGT model is not a general equilibrium model and is not capable of considering even the partial endogeneity of corn price without additional information.

To demonstrate these points clearly, consider the possibility of determining the total impact of an exchange rate change in equation (4). Differentiation obtains

$$(8) \quad \frac{dQ_{ij}}{de} = \sum_{j'=1}^{m} \frac{\partial Q_{ij}}{\partial P_{ij'}} \frac{\partial P_{ij'}}{\partial e} + \sum_{j'=1}^{n} \frac{\partial Q_{ij}}{\partial P_k} \frac{\partial P_k}{\partial e} + \frac{\partial m}{\partial e}.$$

According to the model in JGT, however, the effect of the exchange rate on imports is

$$(9) \quad \left(\frac{dQ_{ij}}{de}\right)_{JGT} = \frac{\partial Q_{ij}}{\partial P_{ij}} \frac{\partial P_{ij}}{\partial e} + \frac{\partial Q_{ij}}{\partial Z_i} \frac{\partial Z_i}{\partial e},$$

where the latter term of (9) includes only two of the

latter n terms in (8)—namely, $\partial m/\partial e$ and $(\partial Q_{ij}/\partial P_{k^*})(\partial P_{k^*}/\partial e)$, where k^* represents corn. Clearly, the true exchange rate effect in (8) can be much different than the JGT effect in (9).

We acknowledge the difficulty of including cross-price effects for all other commodities in estimating (judgmentally or otherwise) any demand equation. Empirical practices often lead to disregarding the less important cross-prices as do JGT. But, again, one must bear in mind that the exchange rate affects perhaps all cross-prices and, thus, while the impact of each individual (excluded) price may be insignificant, the aggregate impact of exchange rate included therein may be very significant. This point, rather than the three listed in GJT (this issue), is the main thrust of our earlier paper which, contrary to their assertion, they have not made previously. It is for this reason that the exchange rate must be given greater flexibility in a trade model than can be allowed by tying its effects to those of wheat and possibly corn prices or, indeed, to any small group of commodities.

Separability does not give one a license to ignore many factors but, rather, leads to a systematic way of including the effects of all factors through the convenience (and tractability) of several aggregate indices. Thus, contrary to the GJT claim that "there is no logical end to this process until all domestic and foreign markets are included," a logical and tractable end as far as including all variables (not necessarily as far as giving each full flexibility) is obtained by correct application of separability theory. For example, the Armington second-stage equation in (5) or (6) gives quantity demanded as a simple function of three variables—one which is commodity specific (P_{ij}), one which is group specific (P_i), and another which summarizes the effects of all other exogenous forces in the economy (m_i or Q_i). Clearly, by equation (1) or (2), m_i or Q_i is possibly affected by every other price in the economy. Thus, to determine the impact of a change in an exchange rate, say e, one cannot simply look at the effects of the exchange rate on the prices P_i and P_{ij} in equation (5) or (6) and their associated impacts on Q_{ij}; one must also consider the effects of the exchange rate on m_i in equation (5) or on Q_i in equations (6) and (7). That is, the total exchange rate impact in the Armington model is obtained only by considering the implications of equations (1) and (2) in equation (5) or (6); in point of fact, using either (5), (6), or (7) in this context clearly implies that

$$\frac{dQ_{ij}}{de} = \frac{Q_{ij}}{Q_i}\left[\sum_{i'=1}^{n} \frac{\partial Q_i}{\partial P_{i'}}\frac{\partial P_{i'}}{\partial e} + \frac{\partial Q_i}{\partial m}\frac{\partial m}{\partial e}\right] - \sigma_i\frac{Q_{ij}}{P_{ij}}\frac{\partial P_{ij}}{\partial e} + \sigma_i\frac{Q_{ij}}{P_i}\frac{\partial P_i}{\partial e}.$$

Hence, calculation of the exchange rate impact for a specific wheat demand requires knowledge of the elasticity (or derivative) of total wheat demand with respect to price indices of all groups of goods, the union of which exhausts the entire commodity set of the economy. Exchange rate impacts, thus, cannot be measured using only a second-stage equation of a separable scheme. Either equations representing both the first-stage allocation such as (1) or (2), as well as a second-stage allocation such as (3), (5), (6), or (7), must be used jointly to determine the full impact of an exchange rate change; or one can simply use equation (4), which is, in a sense, a reduced form of such a joint system. The observant reader will note that each of the possibilities suggested in our paper correspond to equation (4) and thus include, via the concept of separability, the effects of exchange rate on every price in the economy. The point of the meager two paragraphs which dealt with JGT in our earlier paper was that their model might be improved by giving the exchange rate this flexibility.

Turning to the comment by Reed, first note that in our original paper, we attempted to focus on the role of exchange rates in agricultural trade and the implications of trade theory for the modeling of exchange rates in empirical agricultural trade models. For purposes of brevity, we did not attempt to cover other aspects of demand modeling, such as the role of prices of close substitutes or trade barriers, which must be modelled with explicit reference to a given trade problem—sometimes as a departure from (but often not a rejection of) competitive theory. Nevertheless, Reed claims to disagree with our arguments, suggesting that "inclusion of prices of commodities which are close substitutes (complements) to the goods studied and an index of all domestic prices in the countries studied is more sound in theory and practice." Reed apparently insists on full treatment of the usual aspects of demand in addition to the exchange rate issues we raise. He also apparently has missed our note where "for simplicity of exposition, [we] assume that all goods are traded. Although somewhat unrealistic, this assumption does not change the qualitative results of the analysis. It does, however, considerably simplify the notation. The economy of notation hopefully contributes to the heuristic content of the argument" (p. 251). Since our assumption apparently has led to some confusion, however, we will present the general version of our model which includes nontraded goods.

To proceed, write the import demand and supply situation as follows:

$$\text{(10)}\qquad \begin{aligned} D_i &= f(\gamma, \mathbf{p}^*, M)\\ S_i &= g(\mathbf{p}, \bar{\mathbf{p}}, m)\\ Q_i &= S_i = D_i, \end{aligned}$$

where the notation follows our earlier presentation except that $\mathbf{p}^*$ and $\bar{\mathbf{p}}$ are taken to be vectors of prices for nontraded goods in the importing and exporting nation, respectively, and m is income in the exporting country. Now, totally differentiating the equilibrium condition under the assumption that $dM = dm = 0$ and rearranging, obtains

$$(11)\quad \frac{d\mathbf{p}_i}{de}\frac{e}{\mathbf{p}_i} = \frac{\zeta_i}{\eta_i}[(\eta^*_i)'(\mathbf{S} + \zeta^*_i) - (\epsilon^*_i)'\zeta^*_i - (\bar{\epsilon}^*_i)'\bar{\zeta}^*_i + (\eta^{**}_i)'\zeta^{**}_i] + \zeta_i = \tilde{\zeta}_i,$$

where again the notation follows our earlier presentation except that $\bar{\epsilon}^*_i$ is a column vector of cross-price elasticities of supply for the nontraded good prices, η^{**}_i is a column vector of cross-price elasticities of demand for nontraded good prices, and ζ^*_i and ζ^{**}_i are the respective vectors of exchange rate elasticities of the cross prices. Examination of (11) readily affirms that there remains no reason to restrict $\tilde{\zeta}_i$ to the unit interval. Hence, introduction of nontraded goods does not significantly change our qualitative results.

We do not understand what Reed means when he says "that the 'purchasing power parity theory' may not hold," and how this applies to our argument. According to Officer the general theory of purchasing power (*PPP*) implies that short run exchange rates are determined according to

$$es_t = f(PPP_t, \ldots),$$

where es_t is the short-run exchange rate and PPP_t is either the ratio or price levels in the two countries of concern or the ratio of the price indices for the two countries deflated by a base-period exchange rate. Clearly, *PPP* theory implies a causal link between these ratios and the short-run exchange rate. The validity of such a relationship indeed has been the subject of a large literature. However, how this relates to our suggestion to "weight the 'all other' commodity index by the exchange rate" (p. 255) is unclear since our suggestion is simply to deflate some appropriately defined price index for traded goods by the exchange rate, i.e., convert the price index into common currency terms with the other prices in the system. This will not lead to any inconsistency if the index is appropriately defined. What is called into question here is not the *PPP* theory but the validity of the law of one price. That this might not hold at all times because of, for example, barriers to trade, we readily recognize. It is for this reason that in our original paper we noted the Johnson, Grennes, and Thursby "model which takes account of trade restrictions would be a more appropriate setting for examining the importance of exchange rates than the more simple empirical models if sufficient flexibility of exchange rate elasticities *vis-à-vis* price elasticities were allowed." (p. 254).

Reed claims that "the exchange rate change can have indirect effects on all goods in the economy." He argues, however, as though we advocate excluding prices of nontraded goods in estimation of a foreign country's demand for imports. While our earlier theoretical model indeed excludes nontraded good prices for reasons given both above and in our original paper, our interpretation of the results of the simpler theoretical model does not. We, in fact, concluded that "one possibility is to construct separate price indices for 'all other' traded commodities and all nontraded commodities, weight the 'all other' commodity index by the exchange rate, and include both along with the own price (in the importing country) as separate regressors" (p. 255). Thus, we agree entirely with the argument that prices of nontraded goods should be included, if possible, in estimating foreign demand for imports.

We would further argue, however, that use of an index of all domestic prices may not properly deflate the prices of traded goods by the exchange rate and certainly does not consider the possibility of differential rates of adjustment to prices and exchange rates according to the Orcutt hypothesis. Hence, bias could be introduced in the estimation of the exchange rate elasticity of price and of quantity demanded. It should be noted further that some of the simpler models in our paper are proposed for the case where such price indices do not exist and where detailed treatment of demand by country is then infeasible because of data, budget, or time constraints. In these cases, the approach suggested by Reed is not enlightening.

We have argued in our "Critique" that if an index of prices of traded goods is not available, then a feasible but simplified approach may be to "treat the exchange rate as a price index for all other traded goods" (p. 255). Thus, for cases where a domestic price index is available and is representative of price levels of nontraded goods, our work and the model above suggest the same approach as proposed by Reed except that an additional generality is included by adding a separate exchange rate regressor. Thus, the general point made by Reed is, at least implicitly, subsumed in our original paper.

His additional point that prices of close substitutes should be included specifically is simply a further application of the theory of separability which can be made in our framework and with which we fully agree (and, incidentally, fully intended in our original work, although we did not want to take the space to explain already well understood practices in demand estimation). Ideally, one would like to be able to specify a utility function of the weakly separable form $U = F[U_1(D_1), U_2(D_2), U_3(D_3)]$ where D_1 represents the commodity of concern and its close substitutes and complements, D_2 is the bundle of all other nontraded goods and D_3 is the bundle of all other traded goods. The demand functions obtained from such a utility function can then be written as a function of the price indices for groups 2 and 3, the prices of the close complements and substitutes and income. Making similar arguments for the exporting country would then allow us to rewrite (10) as

$$(10')\quad \begin{aligned} D_i &= f(\gamma_i, \tilde{\gamma}, \Gamma, P^*, M) \\ S_i &= g(p_i, \bar{p}, P, \bar{P}, m), \end{aligned}$$

where $\tilde{\gamma}$ is the vector of prices of close substitutes and complements, Γ is the price index for traded

commodities, and P^* is the price index for nontraded commodities in the importing country; $\bar{p}$, P, and $\bar{P}$ are defined similarly. Specification in this manner would not involve bias in the estimation of exchange rate effects or of the role of other prices if the prices of other domestic goods are truly exogenous and the Orcutt hypothesis is not operative.[1] Any indirect effects of exchange rate changes on all goods in the economy would be included explicitly, although simultaneous-equation bias in the estimation of coefficients would occur just as in Reed's proposed model—unless the prices of other domestic goods are truly exogenous.

Finally, with respect to Reed's interpretation of our evaluation of the specification used by Fletcher, Just, and Schmitz (which is also attributed to Meilke and de Gorter in our earlier paper), he claims that we agree. If he will read closely, however, he will find that we do not agree and, in fact, conclude in the context of our theoretical model that "own price would appear denominated in the importer's currency. One can note that this is not the case with the empirical studies discussed below [which refers to Fletcher, Just, and Schmitz, and Meilke and de Gorter]" (p. 255). Thus, our earlier paper, in fact, agrees with Reed that when the very simple, two variable specification is used, a better approach is to include world (or foreign) price and exchange rate. In fact, these arguments were supported in the context of the Orcutt hypothesis (p. 255) which is exactly the phenomena of differential lag effects of prices and exchange rates to which Reed refers in criticizing Fletcher, Just, and Schmitz.

Reed argues that "the excess demand relationship should not be distorted in order to capture the full effect of a change in the exchange rate." We would argue, on the other hand, that respecification of demand equations to capture the "full effect" of a change in the exchange rate is not distorting the demand relationship but, on the contrary, avoiding distortion. We hope that our arguments are not taken as though we do not favor other improvements in demand specification that have been developed elsewhere. In addition to suggesting appropriate exchange rate treatment when sufficient data exists to use other sophisticated specifications with respect to other variables, we simply have attempted to suggest ways in which exchange rate flexibility can be considered where simplicity of specification is dictated by data scarcity, etc. We believe that agricultural economists should not "settle for estimates of partial effects of exchange rate changes," but should continually seek to improve specifications so that empirical results can be less partial in nature and take account of an ever-widening range of phenomena in the general economy which impacts upon the agricultural economy.

[Received August 1979.]

[1] This statement, of course, ignores the existence of trade barriers. In those specific cases where trade barriers exist, they must also be given explicit consideration in econometric modeling. A logical and common approach in economics, however, is to first understand the behavior of a free market so that the effects of market imperfections can be considered in a meaningful way. Such an approach, for example, suggests that a change in the exchange rate may have a substantial effect on a country's import demand because of a demand shift due to prices of other traded goods even though its internal price is fixed by government regulation; this type of effect might be overlooked by simply focusing on trade barriers.

The Value of Unrealized Farm Land Capital Gains: Comment

Richard W. Dunford

In a recent issue of this *Journal*, Plaxico and Kletke (hereafter referred to as PK) analyzed several ways of valuing the unrealized capital gains on farm land. Relatively high rates of appreciation in land values, general price inflation, rising mortgage interest rates, and depressed returns in some agricultural sectors in recent years have enhanced the importance of evaluating land investment decisions. The PK analysis of the value of unrealized farmland capital gains is an important contribution to the work on this issue. However, there are a few conceptual problems with the PK study. Three specific topics are addressed in this comment: (*a*) the relationship between discount rates and inflation; (*b*) the conversion of capital gains into a tax-deferred income stream; and (*c*) the valuation of additional investment opportunities due to the appreciation of land values.

Discount Rates and Inflation

PK (p. 327) defined the present value of anticipated capital gains realized when farmland is sold as

$$(1) \qquad V_0 = \frac{(P_n - P_o)\,(1 - T_c)}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^n},$$

where P_n is the value of the property when sold in the nth year, P_o is the purchase price of the property, T_c is the marginal tax rate applied to capital gains, D is the discount rate as determined by the opportunity cost of capital, T is the marginal income tax rate, and Z is the rate of general inflation in the economy. So, equation (1) stipulates that after-tax capital gains must be deflated by the increase in the general price level, and then discounted back into its present value.

As indicated by Adams (p. 539),

> The appropriate discount rate for individual (unincorporated) investors to use in computing present values is the rate of return available on other assets in the same risk class; this is the opportunity cost of alternative uses of invested funds. . . .

Using the opportunity cost approach, anticipated price inflation will be incorporated implicitly into nominal discount rates. A general inflation results in future returns from investments accruing in depreciated or deflated dollars. Realizing this fact, investors build an inflation expectation into their required rate of return. Therefore, the nominal discount rate for individual investors already includes an adjustment for anticipated inflation.

In equation (1), PK adjust their opportunity cost of capital for anticipated inflation by multiplying $[1 + D\,(1 - T)]$ by $(1 + Z)$, where Z is the general rate of inflation in the economy. Therefore, D must represent the real opportunity cost of alternative uses of invested funds, even though PK do not state whether D is in real or nominal terms.[1] Despite the *de facto* identification of D as a real discount rate, PK in their subsequent examples assume discount rates of 12% and 18% (p. 329). It is not realistic to claim that these are representative real rates of return from investments similar in risk to farmland. However, nominal discount rates of 12% and 18% are realistic when inflation expectations are relatively high. In summary, the opportunity cost of capital in the PK article is specified in real terms in their theoretical model, but nominal values are used in their empirical model.

Capital Gains as a Tax-Deferred Income Stream

As suggested by PK, the unrealized capital gains may be viewed as a "tax-deferred income stream with the tax being paid at capital gains rates when the property is sold or at the end of the planning horizon" (p. 327). Thus, equation (1) can be rewritten in an equivalent specification as

$$(1') \qquad V_o = \frac{\sum_{t=1}^{n} (P_t - P_{t-1})}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^n} - \frac{(P_n - P_o)\,T_c}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^n}.$$

This specification of the present value of unrealized capital gains simply distributes these gains

Richard W. Dunford is an assistant professor in the Department of Agricultural Economics, Washington State University.

Washington State University Scientific Paper No. 5524.

David Walker, Gayle Willett, and an anonymous referee made several valuable suggestions which helped clarify and focus this paper.

[1] It would be double-counting to use a nominal discount rate and then multiply this discount rate by $(1 + Z)$ to adjust for anticipated inflation.

throughout the period of ownership. Because no capital gains are realized until the property is sold, property value increases in the ith year $(P_i - P_{i-1})$ must be discounted from the nth year to obtain their incremental present value.

Valuation of Additional Investment Opportunities

PK state that if some of the increase in equity in land each year is "available as a financial reserve or as an equity base for expansion" (p. 327), there is additional value on a flow basis from the annual equity increases. They claim to incorporate this phenomenon in their equation (2):

$$(2)\ V_1 = \sum_{i=1}^{n}\left[\frac{(P_i - P_{i-1})\,A}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^i}\right] + \frac{(P_n - P_o)(1 - A) - (P_n - P_o)\,T_c}{\{[1 + D(1 - T)]\,(1 + Z)\}^n},$$

where A is the proportion of the increase in equity in land in a given year, due to price increases, that is available as a financial reserve or as an equity base for expansion (p. 327).

PK correctly declare that "equity increases can be viewed as increased reserves which improve financial ratios (reduce the degree of financial leverage) and/or increase financial flexibility" (p. 327–8). They then incorrectly assert that "annual land purchases, or other additional investments are in no way a necessary condition for increased equity to have value on a flow basis" (p. 328). This is incorrect because the benefits received by an investor from a reduced degree of leverage and/or increased financial flexibility have previously been captured in the model.

Since the appreciation in land values is fully anticipated, equity increases over the life of the investment (which improve financial security and flexibility) decrease the riskiness of this class of investments. This reduced risk lowers the opportunity cost of capital on farmland purchases. Thus, the benefits of the reduced risk associated with this class of investments are implicitly embodied in the appropriate discount rate a priori. The "availability" of equity increases produces no additional value unless the increased equity is used to make additional investments.

Because the capital gains on the farmland are not ually realized until year n, it is necessary to orrow to make additional investments. Equation (2) as given by PK does not incorporate borrowing against equity. If the farmland owner only uses his annual equity increases to finance additional one-year investments (as assumed by PK), the present value of the anticipated capital gains would be

$$(2')\ V_1 = \sum_{i=1}^{n}\left[\frac{(P_i - P_{i-1})\,(B)\,(D - r)\,(1 - T)}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^i}\right] + \frac{(P_n - P_o)\,(1 - T_c)}{\{[1 + D\,(1 - T)](1 + Z)\}^n},$$

where r is the contract rate of interest, and $(P_i - P_{i-1})$ (B) is the total amount borrowed.[2]

If the farmland owner uses his accumulative equity increase to finance additional one-year investments, then the present value of anticipated capital gains would be

$$(3)\ V_2 = \sum_{i=1}^{n}\left[\frac{(P_i - P_o)\,(B)\,(D - r)\,(1 - T)}{\{[1 + D\,(1 - T)]\,(1 + Z)\}^i}\right] + \frac{(P_n - P_o)\,(1 - T_c)}{\{[1 + D\,(1 - T)](1 + Z)\}^n}.$$

This equation is identical to equation (3) in the PK article.

Comparison of Alternative Capital Gain Value Estimates

PK use equation (1), (2), and (3) in Models I, II, and III, respectively. Equations (1) and (3) are correct but (2′) should be used in Model II.

Table 1 contains a comparison of the value of capital gains using (2′) as opposed to (2). The following assumptions are identical to those used by PK: (*a*) 5% appreciation in land values; (*b*) 12% discount rate; (*c*) 15% marginal tax rate; (*d*) 0% rate of inflation; (*e*) ten-year planning horizon; (*f*) \$100,000 purchase price of the property; (*g*) 9% rate of interest on borrowed funds; (*h*) B is 1, giving an

[2] B is the ratio of the amount that can be borrowed to the amount of equity needed to support that borrowing. In other words, $\frac{1}{B+1}$ is the equity base required to finance further investment.

Table 1. Annual Values of Capital Gains Over a Ten-Year Planning Horizon: Equation (2) versus Equation (2′)

	Capital Gains			
	Equation (2)		Equation (2′)	
Year	Value	Present Value	Value	Present Value
	($)			
1	5,000	4,537	128	116
2	5,250	4,323	134	110
3	5,512	4,119	141	105
4	5,788	3,925	148	100
5	6,077	3,740	155	95
6	6,381	3,563	163	91
7	6,700	3,395	171	87
8	7,035	3,235	179	82
9	7,387	3,082	188	79
10	7,756	2,937	198	75
Flow value	62,888	36,855	1,604	940
End value	−4,717	−1,786	58,171	22,024
Total	58,171	35,069	59,775	22,964

Note: See table 1 in the PK article.

implied equity requirement of 50%; (*i*) 7.5% tax rate on capital gains; and (*j*) all of the equity increase is available as a reserve for additional investments in each year.

As shown in table 1, the present value of capital gains using equation (2) overstates the actual present value of $22,964, which is calculated by using equation (2′). This present value is based upon annual equity increases being used to finance additional one-year investments. As would be expected, this present value is less than the present value of capital gains when accumulative equity increases are used for additional investments (see Model III, PK, p. 328). The opposite result in the PK article clearly demonstrates the misspecification of their Model II. That is, by using equation (2) in Model II, PK came to the paradoxical conclusion that more value is derived from investing annual equity increases than from investing accumulative equity increases.

In a real world setting, the use of equity increases as a financial base for additional investments usually does not occur on an annual basis. When this type of investment does take place, the term of the investment usually exceeds one year. Thus, a more realistic scenario might involve the farmland owner using the accumulative equity increase at year 5 to finance another land investment with a five-year planning horizon. At year 10, both properties might then be sold. The present value of capital gains resulting from this scenario would fall somewhere between the estimates from equation (1) and equation (3).

In conclusion, under present economic conditions, land values can be expected to increase in nominal (and possibly, real) terms. Even though anticipated capital gains are not realized until the property is sold, equity increases due to appreciation in land values can be used to finance other investments. To the extent that this phenomenon occurs, the present value of anticipated capital gains will be increased. The exact amount of this increase depends upon a multitude of conditions, assumptions, and expectations.

The Value of Unrealized Farm Land Capital Gains: Reply

James S. Plaxico and Darrel D. Kletke

In the current economic setting, evaluation of capital gains is an important issue. In view of the paucity of work relating to the issue, professional dialogue can serve to focus attention on the problem and to contribute to the clarification of underlying issues. The recognition by authors cited in our original paper that capital gains are an important component of land values was a forward step. Our contribution was to suggest that unrealized capital gains have current value and to present two approaches (models) for evaluating unrealized gains. Dunford has raised several questions regarding our formulation and has suggested a modification of one of our models. We are pleased to have an opportunity to attempt to further clarify the issues involved.

Discount Rates and Inflation

Our discount rate (D) is in real, not nominal, terms and is the opportunity cost of capital to the individual (firm) for assets that are comparable in terms of risk and uncertainty. In our analyses we used discount rates (D-values) ranging from 0–24 in order to assess the impact of the different variables on calculated capital gains values using the different evaluation models. In the final draft we included only the 12% and 18% rates to conserve space. The rates used are assumed rates. We have no empirical or other basis for specifying the discount rate of farmland purchasers nor does Dunford provide a basis for asserting that the rates we assumed are nominal rates. We suspect that the appropriate D-value varies among individuals depending on alternatives and capital available, expectations, and individual evaluations of risk and uncertainty.

Some of the confusion in the literature regarding discount rates arises because authors and practitioners tend to combine most or all asset-pricing variables into a single capitalization (not discount) rate. It would be as logical to reflect an expected rising stream of net revenues and/or rising asset prices by adjusting the discount rate downward as to reflect expected inflation by adjusting the discount rate upward. In practice, land appraisers do sometimes combine all factors considered to be relevant into a single capitalization rate. Such a capitalization rate clearly cannot properly be viewed as the discount rate in either real or nominal terms.

It should be noted that the purpose of our paper was to examine the structure of the value of unrealized capital gains. For such an analysis, it is clearly important to identify, within the context of the alternative evaluation models, the impact on capital gains values of the individual variables thought to be important. To combine the discount rate and the expected inflation rate would obscure their separate effects.

Capital Gains as a Tax-Deferred Income Stream (Wealth Value)

Our model II equation (2) is essentially a wealth approach to evaluating unrealized capital gains. The basic argument is simply that an increase in wealth due to an unrealized capital gain has a current value which, when adjusted for an anticipated capital gains tax, could be as high as an equal after-tax income for the same period. In terms of our model II, an $A = 1.0$ implies that a dollar of after-tax capital gains is equal in value to an after-tax dollar of ordinary income. Where current cash flow is a problem, the unrealized gain would have a lesser value than an after-tax dollar of ordinary income, hence an $A < 1.0$. Also, if the unrealized capital gain is not viewed as being secure, that is a subsequent capital loss is viewed as possible, this expectation would be reflected by an $A < 1.0$.

In retrospect our original explanation of Model II invites misinterpretation. We emphasized too much the utilization of unrealized gains as an equity base for expansion. However, Dunford's model embodied in his equation (2′) is a convolution of our Model III and has no relationship to our Model II for which he apparently suggests his (2′) as a substitute. Unfortunately, Dunford has failed to recognize that our Model II is an approach to the evaluation of capital gains in terms of increased (but unrealized) wealth while our Model III evaluates capital gains in terms of the earning capacity of increased borrowed capital based on the equity provided by capital gains in land. This oversight led Dunford to several erroneous conclusions.

James S. Plaxico is State Director, Oklahoma ASCS, U.S. Department of Agriculture, and Darrel Kletke is a professor of agricultural economics, Oklahoma State University.

Oklahoma Agricultural Experiment Station Journal Article No. 3733.

Our Model II embodies a concept similar to the wealth approach of Bhatia, and our Model III is similar to Bhatia's income approach. In short, we reject the usual approach to capital gains (our Model I) because this model assumes a zero current value for unrealized gains. Our Models II and III represent two approaches to the evaluation of unrealized gains. The existence of a current value of unrealized capital gains has been established theoretically (Baquet) and empirically (Bhatia). Baquet (p. 76) treats capital gains as equivalent to income. Bhatia, in estimating consumption functions, derived coefficients that were positive and significant for both realized and unrealized gains although the coefficients associated with unrealized gains were smaller than those associated with income.

As suggested elsewhere "economists frequently ignore the current value of unrealized capital gains because they think of returns as annual income flows and view managers as maximizing a utility function closely related to annual income flows. . . . Wealth accumulation may be superior to income as a simple proxy of the utility surface" (Plaxico p. 1099). The last statement may well characterize a significant number of individuals currently active in the land market.

Capital Gains as the Basis for Additional Income (Income Approach)

It is difficult to imagine a situation that would result in borrowing against an appreciation-generated equity only in the year it occurs. Thus the relevance of Dunford's equation (2′) is not obvious. Assuming a zero inflation rate, Dunford's equation (2′) is identical to our Model II. Thus Dunford's table 1 does not appear to offer additional insight. Further, his conclusions based on our table 1 are incorrect. For example he states, "by using equation (2) in Model II, Plaxico and Kletke come to the paradoxical conclusion that more value is derived from investing annual equity increases than from investing accumulative equity increases" (p. 262). Actually, in our table 1 we compare results from our wealth (Model II) and earnings (Model III) models. Our conclusion is that Model II (the wealth model) generates a higher capital-gains value estimate than our Model III (the earnings model), assuming $A = 1.0 = B$. However, we point out that a comparable degree of leveraging for the two models, i.e., $A = 1.0$ and $B = 3.0$, produces similar estimates from the two models (p. 329).

In our paper we explicitly recognized that in many cases not all unrealized equity would be utilized as an equity base for expansion or for other investments because such equity use often will not occur on an annual basis (p. 327). This was accounted for by the "A" value in our Model II and the "B" value in our Model III. Although not perfect, we consider this approach to be superior to suggesting, as Dunford has, that a "real world" value would fall somewhere between values derived by assuming full investment for one year of annual equity increases and full investment of accumulated equity increases. Elsewhere we have shown the effect of various levels of "A" and "B" values (Kletke and Plaxico).

Conclusions

We can accept readily the conclusion that "the exact amount of this increase depends upon a multitude of conditions, assumptions, and expectations" (Dunford p. 262). However, Dunford has not presented data or rationale that refute the basic logic of our paper. Thus we continue to consider both our Models II and III to be among the reasonable and valid hypotheses of the structure underlying the value of unrealized gains. Hopefully, our paper and the Dunford comments contribute to a better understanding of the issues involved. However, much research of both a conceptual and empirical nature remains to be done.

The Influence of Consumer Price Information on Retail Pricing and Consumer Behavior: Comment

W. H. Lesser and W. K. Bryant

In a recent article Devine and Marion concluded that improved retail food price information during a five-week experimental period in Ottawa-Hull in 1974 caused (in relation to the control market) a reduction in price dispersion among the reported stores, a decline in the average level of prices, and an increase in consumer satisfaction (pp. 230–35). These conclusions, if substantiated, have considerable significance for public policy, especially during periods like the current one of rapidly rising food prices. We believe that the results reported in this study warrant a reappraisal because (*a*) the control in this study (Winnipeg) does not fulfill the statistical conditions normally required for a control, and (*b*) causality between price information and price movements is established through what we consider to be inadequate statistical procedures. We believe also that there are valid alternative explanations for the pricing behavior observed during the experiment and that causality cannot be inferred from the results presented by Devine and Marion (DM).

The authors principally based their conclusions concerning the causal relationship between price information and average price levels on the following observed factors; prices declined more in the test area than in the "control" area (pp. 232–3), and price declines were greater during the six weeks after the beginning of the public price reporting project than occurred during the pre-information period, followed by an increase of 8.8% by the end of the research period (pp. 230, 232).

The use of Winnipeg as a control is questionable because of notable differences in basic characteristics such as the four organization concentration ratio [84.2 in Winnipeg and 71.0 in Ottawa in 1973 (Mallen, table 3–5B)]. Additionally as Blake et al. state in relation to a project designed to replicate the DM study, "spurious effects could readily lead to mistaken conclusions if a single test market were compared with a single control market" (p. 27).

A likely explanation for the observed decline in the DM index during the publication period is the coincidence of the reporting period with seasonal price declines in Ottawa-Hull. Seasonal declines are a common occurrence in Ottawa in October (Food Prices Review Board, p. 18). No mention is made of price seasonality in Winnipeg. In fact the authors' own figure, which uses Statistics Canada data, indicated a price index decline beginning in August, a month prior to the experimental price reporting (fig. 2, p. 233). Thus, the study may have measured a seasonal price decline and attributed it to the competitive effect of price reporting.

DM also exaggerate the overall effect of price reporting by including the decline noted for the week of 2 November with the effective price reporting period (table 1, p. 231). The effective reporting period refers to the date of the report advanced by two weeks, the period considered necessary for the store response to be observable (footnote 1, p. 230). However, 2 November followed 12 October by more than two weeks and followed by more than a week the apparent announcement of the termination of price reporting during the week of 19 October (Food Prices Review Board, p. 9). Thus, this last observation would seem to fall outside the period affected by the experimental price reporting. Excluding it, the total price decline associated with the experiment was 4.8%. From this must be deducted the "2 or 3 percent discrepancy due to sampling error . . ." announced as part of the price reporting program (Food Prices Review Board, p. 35). Thus, the maximum decline attributable to the experiment would have been less than 2%, not the 7.1% claimed by DM (p. 230).

The apparent anomaly between the indexes composed by DM (table 1, p. 231) and that reported by Statistics Canada (figure 2, p. 233) is troubling. For October and early November the DM index is generally flat, while the Statistics Canada (SC) index rises more than one point. Because the market baskets are composed of similar, commonly consumed items (the SC basket included 84 items rather than the 65 items sampled by DM), a possible interpretation is the shifting of margins from those items included in the DM market basket to other products, including those sampled by SC. Such selective shifts in margins seem plausible "because of the possibility that some retailers were able to discern the composition of the (Devine and Marion) basket by the end of the publication phase" (Food Prices Review Board, p. 17). Store management may have been able to discern the basket composition from

The authors would like to thank Joe Uhl for helpful comments and John Morris for providing background information.

those items most commonly consumed by the average Canadian family. Or, as has been suggested by former Food Prices Review Board employees familiar with the study, the price reporter may have acquiesced and revealed the entire item list to store management.

The relationship between interstore market basket price dispersions and price reporting was deduced by comparing dispersions during the effective experimental period with the before and after period. Taking a closer look at the data, the effect of the experiment on price reporting also seems to have been exaggerated. The lowest recorded dispersion (5.4%) did occur during the reporting period, but the average percent spread of 7.7% during the effective reporting period (28 September–26 October) was higher than for two five-week periods in the prepublication phase (7.8%, 7 June–5 July and 7.5%, 26 July–23 August). Because spreads were quite volatile during the reporting period the comparison of average spreads over periods of the same length would seem to be preferable to the authors contrasting averages from the twelve-week period prior to the five-week publication period (p. 232). Thus, price reporting did not have a clearly positive effect on reducing price spreads among stores.

Our concerns reduce to a disappointment that DM did not do a more complete statistical analysis of their data. Their's is a gross analysis of the data, when what is needed is an estimate of the net effect of price reporting holding other factors constant. A more thorough analysis would include a means of adjusting the data for seasonality either by using index deflators or proper employment of controls and allowing for shifts in store ranks and margins which occur independently of the reporting experiment.[1] The application of these procedures will provide less ambiguous insights into the short-term relationship between food prices and improved information.

[*Received July 1979: revision accepted August 1979.*]

[1] One model specification that incorporates the suggested modifications is as follows:

$$P_{tj} = a_0 + a_1 T_{1t} + a_2 T_{2t} + a_3 T_{3t} + \sum_{i=1}^{J-1} a_{4i}\, SD_{tj}^{i}$$
$$+ \sum_{i=1}^{J-1} a_{5i}\, SD_{tj}^{i} T_{1j} + a_6\, SR_{t-1,j} + a_7\, RP_{tj} + a_8 SR_{t-1,j}\, RP_{tj}$$
$$+ \sum_{i=1}^{J-1} a_{9i}\, SD_{tj}^{i} SR_{t-1,j} RP_{tj} + e_{tj},$$

where

P_{tj} is weighted price index in week t in store j;
T_{1t} is t, a linear trend variable;
T_{2t}, max $(T_{1t} - 11, 0)$;
T_{3t}, max $(T_{1t} - 24, 0)$;
SR_{tj}, rank of store for store j in week t, a rank of one indicates the lowest price store;
SD_{tj}^{i}, 1, if observation is from store i ($i = 1, \ldots, j-1$), 0, else;
$RPtj$, 1, if observation is from reporting period, 15 September through 12 October, 0, else;
e_{tj}, random disturbance term.

The first three variables control for trend and seasonality. Systematic differences in price levels among stores are captured by the store dummies, SD_{tj}^{i}, while the interaction between store dummies and the line trend, $SD_{tj}^{i}T_{1t}$, measures systematic alterations in marketing strategies. Overall adjustment to price reporting will be caught by the period dummy, RP_{tj} while the interaction between store rank and the period dummy, $SR_{t-1,j}\, RP_{tj}$, captures the specific effect of publishing ranks. The last term, $SD_{tj}^{i}\, SR_{t-1,j}\, RP_{tj}$, is designed to pick up store specific differences in response to the reporting experiment.

The Influence of Consumer Price Information on Retail Pricing and Consumer Behavior: Reply

D. G. Devine and B. W. Marion

Although in the main we disagree with the comments of Lesser and Bryant (LB), we welcome the opportunity to discuss further some of the points they have raised. The influence of increased information on the performance of oligopolistic markets is relatively unexplored, either theoretically or empirically. Dialogue and debate should be encouraged.

LB make several criticisms of the methodology and interpretations of our study. We will discuss them in the order that they are raised.

The use of Winnipeg as a single control market is questioned. We acknowledge the experimental design limitations of a single test-single control experiment. In order to test for internal and external validity, a four-market design was originally planned (two test and two control). Unfortunately, the Food Price Review Board would agree to only a two-market design; we are, therefore, unable to determine if the pretest consumer survey in the test market influenced the response of consumers to the price comparison program and/or affected their answers to the post-test consumer survey. Given the nature of the consumer questionnaire and the relatively small percentage of consumers who answered it, it is doubtful that it significantly affected the market response of consumers to the price comparison information; however, we have no way of testing this assertion.

Given this limitation of the research design, we do not agree that Winnipeg was an inappropriate control market. Winnipeg and Ottawa (the test market) are comparable in population, similar in their French and English cultural backgrounds and sufficiently separated spatially so that the control market was not influenced by the test market treatment. The four-firm concentration ratios, while not identical, were very high in both markets (84 and 71, respectively). The difference in four-firm concentration would be of greater expected importance if the level of prices in the two markets were being compared rather than the change in price. Although there are theoretical grounds for expecting price adjustments to be different in concentrated oligopolies than in competitive markets, there is no theoretical or empirical basis for expecting that short-run price changes within two highly concentrated oligopolies will be significantly affected by differences in market concentration.

One possible limitation of the two markets selected is the difference in the sources of supply and, hence, the possibility of different seasonal price patterns. This brings us to the second criticism of LB—that causality between the price information program and price declines in Ottawa-Hull was not adequately demonstrated because price seasonalities were not considered. This is a valid concern in any temporal pricing study. Food prices in Canada have shown a seasonal decline in September during the 1970s. Statistics Canada's monthly food price indices for Ottawa, Winnipeg, Toronto, and all Canada for the seven years 1971–73 and 1975–78 are shown in figure 1. Although there are slight differences in the seasonal patterns in the three metropolitan areas, they are generally similar. Compared to the August price indices, September prices average 1.26% lower in Ottawa, .40% lower in Winnipeg, 1.23% lower in Toronto, and .90% lower for all Canada. September and October indices are essentially identical in all three of the metropolitan areas. Based upon these data, any substantial differences in price movements in Ottawa relative to Winnipeg are unlikely to be due to differences in seasonal price patterns.

Although prices in Ottawa and all Canada typically have a seasonal dip in September, this is not true in all years. In 1974, Statistics Canada's price indices for food consumed at home in all Canada rose monotonically from 137.7 in April to 153.3 in December (1971 = 100). Price indices for Winnipeg and Toronto also showed a consistent upward movement throughout this period. In Ottawa, however, Statistics Canada data indicate a drop in price in September followed by a further drop in October (figure 2). There is no evidence that these declines are due to seasonal price movements.

There are other reasons why it is difficult to consider seriously LB's seasonality contention. First, it flys in the face of simple logic. A credible and simple comparison of prices for one-half of the supermarkets in a city would have no effect on prices only if consumers and retailers did not respond to such information. The only situations in which this seems conceivable are either where the

Figure 2. Consumer price index of food at home January 1974 to February 1975 (1971 = 100)

distribution of prices perfectly reflects the perceived value of the product-service offers of different retailers, or where perfect collusion exists. Both are unlikely in our opinion.

In addition, our first-hand experiences in conducting the study are helpful in assessing causality. During the information-publishing period, retailers phoned the Food Price Review Board daily to check on their standing or to complain about losing sales. Consumers called to obtain information on store ranks and price changes. Retailers and their lawyers addressed the Board en masse to complain about the cutthroat competition being imposed upon them. Some threatened lawsuits. It was obvious to anyone in the market that something dramatic had happened. It was certainly not a seasonal event.

Because of the way figure 2 in our article was drawn, LB mistakenly conclude that the price decline in Ottawa began in August. Statistics Canada collects data only once a month during the first week of each month. Thus, the price decline occurred in early September. Even with this correction, however, LB are correct in noting that Statistics Canada indicates a price decline in Ottawa before the start of the price information program. In addition, Statistics Canada data indicate a somewhat different price pattern during September-November than the price data collected as part of our study. Although we have reexamined the sampling and weighting procedures used in developing the two data sets, we are unable to account for this difference. There are several differences in the methodologies: the sampling and weighting of stores, and the number, brands, and weighting of products price checked. Thus, the two data sets are expected to exhibit some differences. However, they are also sufficiently similar that the same basic price patterns should be evident. Without data on the stores, products, and brands actually price-checked by Statistics Canada, we are unable to reconcile the differences. We are confident of the accuracy of the price data developed by our price check teams. Enumerators were carefully trained, observations were randomly double checked for accuracy, and the items and brands to be checked were carefully specified. A 2% to 3% error for individual store indices was the maximum encountered.

LB misinterpret this error percentage as applying to the average price index for Ottawa-Hull. Because this was the maximum error for individual store indices, the average calculated for twenty-six stores would be expected to contain offsetting errors. The maximum error expected for the price index for the total market would be much smaller than 2%–3%.

LB indicate the overall effect of price reporting was exaggerated by including the week of 2 November in the calculation and ignoring the error margin discussed above. Although no price comparisons were published during the week of 26 October, retailers and consumers were not informed of the cessation of the program until the latter part of the week of 2 November—the time when price checks were being made for that week. Price

changes made early in that week (retailers generally make weekly price changes on Monday–Wednesday) may well have assumed the price comparison program was still in operation. In addition, neither theory nor empirical evidence defines the promptness nor duration of competitive responses to disequilibrating stimuli. Given the shift in patronage that occurred as a result of the price information program and the continuation of price monitoring through October and November, the competitive behavior of retailers may have been influenced by the information program for several weeks after publishing was ceased. Thus, our estimates of the overall effects of the program—while hardly precise—do not appear to be exaggerated.

LB also contend that the estimated effects on price dispersions in Ottawa-Hull were exaggerated because a twelve-week rather than a five-week period was used for comparison; in addition, the selected period was immediately prior to the information program. There is no uncontestable procedure for selecting a base period to compare with the test period. The average price dispersion of 7.8% during the information program could have been compared with the average dispersion during the five-week period prior to the program (11.4%), the twelve-week period prior to the program (9.7%), the entire nineteen-week pretest period (9.4%), or several other arbitrarily selected periods.[1] Our estimate of the information program effects may be incorrect; however, one can argue as easily that it is understated as that it is exaggerated.

Finally, LB express their disappointment that we did not do a more complete statistical analysis of the data and suggest a model that would provide estimates of the "net" effect of an information program. The appropriate statistical analysis for such an experimental venture is not easy to define. We welcome the ideas and suggestions of others. In this case, we do not feel that LB have demonstrated that our analysis was deficient or that their model holds promise for more penetrating and accurate interpretations. Their main criticism of merit is the inconsistency noted between the two price data sets. This is a data problem, not a statistical analysis problem.

A model similar to the covariance model suggested by LB was applied to a price information study in Saskatchewan during 1975–76. Such models are designed on the premise that each cross-sectional unit and each time period are characterized by their own special intercept (and/or slope). As Kmenta states, "If the model is correctly specified and the classical assumptions are satisfied, the OLS estimates . . . will be unbiased and efficient" (p. 517). The problem is accurately specifying the model for an oligopolistic market environment. Experience in applying the model to the Saskatchewan study revealed serious specification and multicollinearity problems, particularly for the slope and intercept dummy variables. When both dummy variables were included in the model, coefficient estimates were highly unstable.

Where a price comparison information program is a one-time intrusion into a market operation, we believe pricing behavior in carefully selected control markets is more likely to reveal the effects of nonexperimental factors than the inclusion of seasonal dummy variables. Seasonal price patterns vary considerably from year to year. In the Ottawa case, use of the LB model with a seasonal dummy might have indicated erroneously that the price decline was due to seasonal factors when in fact no seasonal declines were evident in other Canadian cities. We also question the inclusion of an independent variable on store rank which is linked to the dependent price index itself. Accurately specifying the appropriate time lag in a store rank variable could prove difficult because the lag in firm response may change over time and may vary from firm to firm.

With greater experience, models of the general type suggested by LB may be modified so as to provide more rigorous analysis of price information experiments. To date, however, simpler statistical analyses have provided the most useful and consistent insights.

[*Received December 1979.*]

[1] An unexpected benefit of reexamining table 1 in our article is the discovery of several errors. The correct percentage differences are as follows:

	Ottawa-Hull by Firm	Ottawa-Hull by Store
19 May		13.40
7 June	5.80	8.76
21 June	3.62	5.99
2 August	3.67	
9 August	4.16	6.49
14 September	6.82	
30 November	6.14

Welfare Impacts of Milk Orders and the Antitrust Immunities for Cooperatives

Robert T. Masson and Philip M. Eisenstat

Many agricultural programs are being seriously reconsidered, including the Capper-Volstead partial antitrust exemption for cooperatives and the Federal Marketing Orders. We focus on the dairy industry, concentrating on the interface between monopoly, the Capper-Volstead Act, and the Orders. Using social cost-benefit analysis, we estimate that in the 1970s cooperative milk monopolies cost society more than $70 million a year, and that the Orders are partially responsible for these monopolies. These monopolies could have been avoided, and, once eliminated, could be avoided in the future with small changes in the Capper-Volstead exemption.

Capper-Volstead and Federal Milk Orders: Their Goals in Perspective

The Capper-Volstead Act of 1922 had two basic goals. The first goal was "that individual farmers shall be given . . . the same unified competitive advantage—and responsibilities—available to businessmen acting through corporations as entities" (*Maryland and Virginia Milk Producers* 362 U.S. 466). Without the Act, farmers who acted jointly in marketing would have run afoul of the Sherman Act unless they merged their farm assets. The second goal was "equalizing the bargaining power of the individual farmer in the relatively more concentrated markets in which he buys and sells" (National Committee, p. 208).

Under the antitrust laws neither corporations nor cooperatives are prohibited from possessing monopoly power, but neither may "monopolize." Monopolization is generally defined as predatory, coercive, and exclusionary acts and practices used to gain or maintain market power.

Corporations may not undertake mergers or joint ventures that have a significant probability of creating market power. Cooperatives may be exempt from the law in these areas and have generally not been challenged in them. As Assistant Attorney General Donald Turner stated, when merger "seems equivalent to the voluntary enrollment of new members" because at the time of merger "each member . . . is free to withdraw and to be reimbursed the value of his share . . . ," then merger would appear to be permitted. Creation of monopoly power by merger or joint venture appears to be legal for cooperatives, at least *de facto* if not *de jure*.

The Orders were codified in 1937 to provide: (*a*) orderly marketing, (*b*) an adequate supply of milk, and (*c*) an increase in farmers' incomes. These goals were not absolute but were to be balanced against "the public interest." They reflect the technological and economic conditions of that time and need to be reevaluated in the light of current conditions (Masson and Eisenstat; Alagia).

The milk markets of the 1930s differed substantially from today's markets. A prospective buyer could not phone a farmer, a cooperative, or a broker and expect them to deliver high quality milk over any distance. Coops

The papers in the "Proceedings" section were presented at the winter meeting of the AAEA held in conjunction with the Allied Social Science Associations in Atlanta, Georgia, 28–30 December 1979.

Robert T. Masson is an associate professor of economics at Cornell University; Philip M. Eisenstat is an economist with the U. S. Department of Justice.

This article represents the views of its authors and is not to be construed as representing the views of any agency of the United States Government.

were still forming; before pasteurization, a buyer had to know and have confidence in each source; many rural areas did not have phone systems; farms lacked refrigeration; trucks were slow and roads circuitous; and farmers did not have the technology to verify how much milk they sold or the butterfat it contained. Along with severely depressed farm income, these conditions led to localized and often unstable markets.

Today's technology and economic conditions would not produce market disorder as conceived in the 1930s. However, the U.S. Department of Agriculture (USDA) now treats "orderly marketing" as synonymous with "regulated marketing"; "disorderly" includes even desirable aspects of perfect competition (Dobson and Salathe).

Because the markets of the 1930s sometimes failed to supply enough milk of sufficient quality for fluid consumption, the Act was designed to assure that consumer demand for fluid milk was met. Again, as technology has shifted, so have USDA's definitions. Now USDA asserts a need for an adequate supply of milk for all uses (Masson, pp. 23–39). The Department dismisses the traditional indicators (USDA 1977, p. 29) which show massive surplus (Dobson and Buxton, pp. 8–11; Masson, pp. 23–39). And as will be seen, the demand for milk for all uses has been grossly distorted by the Orders.

The need to raise farmers' incomes through such programs should be reexamined now that the gap between average dairy farm income and average urban income has disappeared. If average dairy farmer income were equivalent to average urban income, then dollar subsidies would flow from poorer consumers to richer farmers. The income elasticity of demand for milk is close to zero, so the "tax on consumers" is a regressive poll tax, whereas the subsidy to farmers is proportional to farm size and wealth: the 3.3% largest dairy farms receive more subsidy dollars than the 44.8% smallest. Manchester shows that dairy farmers currently earn 40% more than their urban counterparts (even excluding capital gains), radically shifting the balance between the dairy farmer and the consumer (pp. 28–30). Even given a case for continued regulation, prices could be lowered significantly and still satisfy the first two goals. In this case the public interest must balance the farmer income goal against the consumer's welfare, a balance which has shifted radically over the years.

The Theory of Income Enhancement, Market Power, and Social Costs

In the 1930s Gaumnitz and Reed presented a model to show how monopolistic price discrimination could enhance dairy farmer income and rents when farmer supply could not be restricted. Price is raised for fluid or Class I uses of milk where marginal revenue is low, and the rest of the supply is dumped into Class II (butter, powder, ice cream, etc.) manufacturing uses where marginal revenue is higher. This principle underlies the Orders.

Price Discrimination and Income Enhancement

In unregulated competition a homogenous commodity will sell for a single price regardless of end use. This will be true even when the demand for the product is different for different uses. When a buyer uses a product for dissimilar purposes, the single price generally (though not universally) implies that marginal revenues differ between submarkets defined by use. Total revenue can be increased for any output by shifting product from a low to a high marginal revenue market. If this is accomplished, average revenue will be higher than it would have been under competition at all output levels. If each unit of sales shares these increased revenues equally, an average revenue curve is established above the demand (unregulated average revenue) curve. Monopoly power restricts the quantity of Class I milk. Because the higher average revenue induces an expansion in the supply of milk, the new equilibrium has both higher quantity and higher price unless the supply is infinitely elastic. Although farm profits return to zero, this will be due to rising Ricardian rents (Buxton; Ippolito and Masson, p. 50).

Social Costs of the System

This price discrimination raises price, *PI*, for Class I milk and suppresses price, *PII*, for Class II milk, thus raising social costs. Assume that at some current margin the Class I price exceeds the Class II price. Then assume that the Class I price is raised sufficiently that one fewer unit of Class I milk is purchased. One social effect is the lost value of that unit of milk in the Class I market, *PI*, net of the value of that unit of milk in its alternative Class II use, *PII*. Induced supply expansion is also

costly. Individual farmers are price takers, so the marginal cost of output expansion is equal to average revenue. The social cost of supply expansion is thus the average revenue or "blend price," Pb, times the induced change in supply, dQ_s, net of its value in use, the Class II price. Hence the marginal social cost of a unit of milk taken from Class I is $SC = (PI - PII) + (Pb - PII)\ dQ_s$.

These principles have been used to solve for the deadweight losses of the Orders and for transfers from consumers to farm rents by Ippolito and Masson; Buxton; Hammond, Buxton, Thraen; and others. Ippolito and Masson arrived at minimum bound estimates of approximately $25 to $30 million a year of social costs due to the deadweight losses. Other estimates have varied from a low of about $10 million.[1] In addition, regulatory expenditures amount to at least $34 million a year. Although the Orders raise farm income, they do not maximize farmer income. This leaves room for monopoly power. Regulated prices PI and PII yield average revenues of Pb through a mechanism by which buyers pay a government Market Administrator (MA) PI for all milk used for Class I, QI, and PII for Class II, QII. The MA "pools" all the revenues over the milk total, QT, and pays the price $Pb = (PI\ QI + PII\ QII)/QT$ to the farmers or their cooperatives.

Now assume coop A controls 100% of a market and, for simplicity, that PI and PII are parametric. The coop may increase revenues by charging a premium, D, above the regulated price PI. If these revenues were also collected and pooled by the MA, then QI would fall due to the higher price $PI + D$, and both QII and QT would rise. However the MA does not collect these revenues, so a coop can achieve premiums only on milk it sells as Class I. If a competitor makes a sale, only the competitor receives that premium revenue. In addition, both the coop and the competitor receive Pb from the MA.

In most markets some buyers only purchase Class II milk, while others purchase both Class I and Class II milk. The latter are called "fluid handlers." A coop ships truckloads of homogenous-commingled milk to fluid handlers who pay $PI + D$ for units put into Class I and PII for Class II. The coop receives $Pb + D$ for Class I and Pb for Class II, but each unit in the load was associated with a single marginal cost. This type of price discrimination requires market power in excess of the buyer's power. (Strictly speaking, D is actually the excess of any Class I premium over any Class II premium.) To countervail power means to offset power. Monopsonists restrict purchases, driving the supply price below the demand/marginal revenue product curve. Countervailing a monopsonist's power pushes price up to the demand curve but not above the supply curve and quantity increases to clear the market where demand equals supply/marginal cost. In contrast, raising D pushes price above marginal (opportunity) cost and decreases fluid handler purchases. Also, if D simply countervailed buying power then $Pb + D$ would be the competitive price (given regulation). Class II users would then be revealed as monopsonists.

Define U^k for the k^{th} seller as the proportion of k's milk, which is used in Class I, or k's "utilization rate." We now assume that a coop A has an intra-order competitor, C. The total market utilization rate is $U^m = S^a U^a + S^c U^c$ where S^k denotes k's market share and $S^a + S^c = 1$. If k has a cost of doing business of X^k per hundredweight (cwt), then the net return per cwt, r^k, of being a member of k is:

$$r^k = Pb + D^k U^k - X^k \qquad k = A, C.$$

Let us also assume that each handler sees a cost of doing business with group k as Y^k per cwt purchased. The handler's cost is $PI + D^k + Y^k$ for Class I and $P_{II} + Y^k$ for Class II. The handler's iso-cost between A and C is $D^a U^h + Y^a = D^c U^h + Y^c$ where U^h is the handler's utilization of Class I milk.

Now let us model competition. We shall initially assume that QI and QT are constant so U^m and Pb do not vary. Let us say that initially $S^a = 1$ but a group of members is considering agreeing to withdraw from A to compete. They will raise their income only if they achieve a D^c such that $D^c U^c - X^c > D^a U^a - X^a$. If this group needs to equilibrate costs to the handlers to make sales, they will not compete if:

$$D^a < [(X^c - X^a) + (Y^c - Y^a) U^c/U^h]/(U^c - U^a) = D^a{}_p.$$

This establishes the barrier to new competition or the "protected premium," $D^a{}_p$.

[1] Our study included all U.S. milk, including state orders, and assumed that the grade A price would exceed the grade B price by about $.30 in Eau Claire and more elsewhere. Other studies have looked only at Federal Orders and assumed a wider grade A differential. Also, Buxton assumes that supply is highly inelastic: .14. A low elasticity raises measured farmer rents but lowers measured social costs as dQ_s is smaller.

In a frictionless system $X^c = X^a$ and $Y^c = Y^a$, so competition is preferable to membership as long as $U^c > U^a$ may be achieved. D^a_p is sensitive to the X^k's, Y^k's, and U^a. If $U^c = U^h = 1$, then the protected premium is $D^a_p = [(X^c + Y^c) - (X^a + Y^a)]/(1 - U^a)$. If the numerator or "gross cost disadvantage" is \$.10, then D^a_p is \$1.00, \$.50, or \$.20 as U^a is .9, .7, and .5. A gross cost disadvantage of \$.20 would double D^a_p. Modest artificial impacts on the X^k's and Y^k's can radically alter D^a_p.

How Regulation Creates and Maintains Market Power

Part of the key to milk cooperative market power is operating in several milk markets. Coop A's revenue in any market is

$$R^a = \left[\frac{PI(QI^a + QI^c) + PII(QII^a + QII^c)}{QI^a + QII^a + QI^c + QII^c}\right] (QI^a + QII^a) + QI^a D^a,$$

so if a coop took a unit of Class II milk from Market 1 to Market 2, its marginal revenue would be

$$MR_2{}^a - MR_1{}^a = S_2{}^c U_2{}^m (PI_2 - PII) - S_1{}^c U_1{}^m (PI_1 - PII).$$

For example, if $S_1{}^a = 1$; $S_2{}^a = .75$; $X_1{}^a = X_2{}^a$; $(PI_1 - PII) = (PI_2 - PII) = \$2.00$; $U_1{}^m = U_2{}^m = .7$; and both markets were of equal size, then by moving 22% of the milk out of Market 1 into Market 2 the coop could "reblend" its revenues and continue to pay its original Market 1 producers the same net blend price, $r_1{}^a$, as before and pay its Market 2 producers \$.26 per hundredweight more than before. If there were no threat of competition in Market 1, the coop could hence artificially create an $X_2{}^a = -.26$ so even if $X_2{}^c = 0$, $(X_2{}^c - X_2{}^a) = .26$. Using an assumed $X^c = Y^a = Y^c = 0$ then Market 2, which without manipulation had no market protection, now has market protection, for $D_2{}^a < 60$. The members of C can increase their revenues by joining A! All other things being equal, a cooperative with a dominant share in one market has regulatory incentives to pool milk on markets where it has more competitors. This incentive is reduced, the more milk has to be physically shipped between the markets to effectuate this shift. For many market pairs, the necessary shipments are low. In some markets, if a coop ships milk from Market 1 to Market 2 for one or two days, the coop's milk subsequently would be pooled as Market 2 milk even if no further shipments to Market 2 take place.

Why do the regulations permit such pooling? Given price regulation, such pooling regulations are needed for efficiency. The cost of transporting milk is far higher than the cost of transporting Class II products. Given the seasonality of production, farmers located far from city centers needed to be encouraged to produce fluid grade milk so the cities would have enough milk during low production fall months. This encouragement took the form of granting them the blend price. If during the spring they had had to ship their Class II milk to the city to receive the blend price, that would have been an inefficient transport of milk for Class II use rather than Class II products. Guidelines were developed to decide which farmers needed to be encouraged to produce to fulfill the needs of these markets during the fall. USDA is faced with a quandary: the more it requires actual shipments to demonstrate backup potential, the less a market can be manipulated—but the less efficient the handling of the true backup supply.

Such cross-market pooling drives down the prices received by competitors of a multimarket dominant cooperative. As we have noted, reblending manipulates X^a and reduces the incentive to compete in markets where there is significant competition. Particularly in markets with traditionally high utilization rates, moderate changes in the X^a's reduce the incentive to undercut monopoly premiums substantially. The lower prices received by competitors are not reflected in lower consumer prices, but rather in power to charge even higher monopoly prices.

Even moderate manipulation of the pooling provisions can create large changes in D^a_p's. In recent testimony Associated Milk Producers, Inc. (AMPI) explained how they shift pooling in this fashion.[2] Baumer showed that high market shares lead, *ceteris paribus*, to higher intramarket utilization (i.e., pooling surplus elsewhere). (See also Masson, pp. 100–2.)

---

[2] Testimony of AMPI's Joe E. Murphy and Kiefer Howard. Record, *In the Matter of Proposed Marketing Agreements and Orders Regulating the Handling of Milk in the Texas Marketing Areas.* USDA Docket No. A0-231-A45 et al., 7 Apr. 1977, Irving, Tex., pp. 602 (Murphy), 867 (Howard). See especially pp. 702, 786–90, 801, 879, 895–97, 907-8 and 912.

Before actions by USDA and the Department of Justice (DOJ), this type of manipulation was far more pronounced. Cross market-pooling was pursued to drive competitors out of markets, and was referred to as "pool loading."

An example is useful.[3] In 1967 AMPI started to load the Oklahoma pool, dropping U^m from an annual average of about 67% to 57% starting in September. While many farmers were driven into AMPI, part of the target group was able to use the order provisions to avoid regulation and the pool loading. In 1969, AMPI succeeded in voting an amendment to the order provisions which repooled these producers. In 1970, it pooled Class II milk from Iowa, Minnesota, and Wisconsin on the Order. By physically shipping one day's production to the market, the entire production of those farmers was pooled on Oklahoma for subsequent months even though it remained in its original geographic area. The utilization rate dropped to an annual average of 47% as AMPI "paper pooled" 36 million pounds a month in addition to its indigenous supply of 45 million pounds a month. This enabled AMPI to reblend well above the depressed market blend price. By September of 1971, only around 40 of more than 160 farmers remained as competitors.

In some cases, due to costs, prices, or market shares, changing market pooling to drive down competitors' prices was not profitable. In these cases, for the same reasons, regulation reduced the costs of predation. For instance, traditional north Texas milk could be pooled on south Texas simply by changing some computer cards in AMPI's accounting system. From 1971 through at least 1974, this technique decreased U^m by over 20%, cost AMPI about $30,000 a month, but took almost $40,000 a month of competitors' pool revenues.[4]

Flexible pooling comes from a need, given regulation, to promote efficiency. Although this flexibility is no longer manipulated in a predatory fashion, the moderate repooling flexibility inherent in the system helps protect monopoly premiums by reducing incentives to compete.

The order system protects market power in other ways. If competition has been eliminated (either by monopolization or by voluntary merger), the dominant coop must worry not only about intra-order competitors but also inter-order competitors. The order system reduces inter-order competition as well.

Consider the options available to a buyer facing a full supply, all-or-nothing contract demand from a dominant cooperative. If intra-order supplies are controlled by the coop, the buyer must look to other markets.

Sellers in other areas could sell milk directly to the buyer and become pooled on the buyer's market. Were they to do so, they would increase S^c and shift the balance of MR's across markets. The coop then has the same incentive to pool additional milk on that market. The competitor will receive the reduced price as it is now an intra-order competitor. The competitor might then be better off returning to its originating order. If it were to do so, the cooperative's power would be reestablished, the buyer having lost its supply. Also, provisions in an originating order may inhibit a return, leaving the sellers no defense against the lower price. Sellers may not be willing to take this chance.

Alternatively, a potential seller may buy and pool milk in its traditional market and then resell or "transfer" this milk to the buyer. USDA regulates such sales to keep sellers in one market from undercutting those in another, increasing transport costs and destroying the natural milk supply for that market. Hence they created a "tax" on such sales, which is lower if the receiving market has a shortage (i.e., a very high U^m). This was efficient because without monopoly power, milk transport between markets is inefficient unless there is a shortage. But monopolies take advantage of this tax. Consider a buyer who is purchasing both Class I and Class II milk. The buyer then desires more Class I milk, but this milk carries a premium of D^a, while less expensive milk is available in another market. The buyer then buys milk by a transfer from this other market. Part of the milk is then "down allocated," i.e., allocated "down" from Class I to Class II. The MA in the receiving market treats the increased Class I milk as having come from the dominant coop (not the outside) and the Class II milk as com-

[3] Sources for all examples using AMPI are cited in Eisenstat, Masson, and Roddy. *U.S.* v. *AMPI* was settled out of court, the authors were not subject to cross-examination, and AMPI does not admit to the allegations contained in this report. The reader should also be aware of the critique by Cook, Blakley, and Berry. However this critique does not examine evidence of intent (p. 1), which is the focus of the original report.

[4] USDA (1977, p. 32) claims credit for stopping pool loading in 1971. However some pool loading continued, in this case until 1974 (Masson, pp. 96–100).

ing from the outside. The buyer will receive a premium bill which is still high (it did not achieve the lower premium because of the down allocation) and it will pay into the pool the Class I price, raising the blend price received by the coop. (Additional transport absorption costs are inherent in down allocation as well.) Limitations on down allocation reduce it when U^m is high. This acts like a tax paid to the MA when buying out-of-market supplies.

Down allocation creates a barrier to entry for new intra-order competitors. If a market requires outside milk, the "tax" must be paid on it and the subsidy spread across all order farmers. Hence, for buyer k the cost of outside milk is $t(1 - S^k)$ per unit of milk, where t is the tax per unit. A proprietary buyer does not sell raw milk so it pays t per unit, a coop with 5% of the market $.95t$, and a coop with 85% only $.15t$. AMPI, for instance, had over 90% of the market in ten of its sixteen southern markets and over 70% in thirteen of them in 1973. Pointing to "large" inter-order flows of milk (1976), USDA says that down allocation does not create a barrier. (When U^m is high this may be true; however, U^m is not always high.) But because a dominant coop only pays a fraction of the tax paid by competitors, statistics showing inter-order milk movements are no gauge of inter-order barriers to entry unless all dominant cooperative movements are deducted.

A final source of outside competition used to be unregulated milk from the far north, M-W milk. Unregulated producers could not lose by pooling on an order because if the pool were loaded they could withdraw without cost. Prior to 1967 this milk could undercut premiums to draw higher blend prices. (Eisenstat, Masson, Roddy.)

In 1967, several cooperatives taxed their members to pay M-W producers not to ship milk unless asked by a contributor. This "standby pool" was said to be a contractual reserve supply needed to avoid having to pay up to $1.00 extra for outside milk in case of shortages. Shipment data and receipts show that these coops paid well over $5.00 extra per hundredweight for milk actually shipped ("reserve payments" over time plus actual point of shipment costs), and many paid far more.

The 1975 consent decree with AMPI substantially reduced the effectiveness of the standby pool. By that time, increased transport costs also had reduced the importance of this milk as a competitive force. Further, in 1976, USDA established a new milk order, order 68, for that previously unregulated area. The order provides for a power to require plants to ship to other areas when there are shortages but inhibits shipments otherwise.

Cooperative Exemption Far In Excess of That Intended

In the last decade some milk cooperatives held market power far in excess of countervailing levels. This cannot be rationalized on the basis of a public interest in raising depressed farmer income; it has been bolstered by the Orders, and it could have been avoided by jurisdiction over cooperative mergers and joint ventures.

AMPI was formed by a series of over ten major mergers starting in 1967. In the next three years AMPI merged with fifty-four additional coops. Some of these mergers were coerced; some were voluntary (Eisenstat, Masson, Roddy). Had the agglomeration been based on freedom of individual farmer membership, it would have succeeded only where there were efficiency gains. Because individual freedom of membership is inherent in the system, the cost to society of prohibiting large market-share mergers is far lower in cooperative ventures where members may leave less efficient coops than in proprietary ventures where less efficient firms may survive.

The growth of some dairy cooperatives in the last decade can be compared with the growth of firms like Standard Oil and U.S. Steel near the turn of the century. Like AMPI, Standard Oil mergers led to predatory and exclusionary practices. But the growth of U.S. Steel resulted in just as undesirable results, despite the lack of "bad acts." Because of the absence of bad acts, U.S. Steel was ruled innocent of monopolization despite the large market share it had acquired. U.S. Steel used its market power to charge higher prices than competitors for decades, letting its market share slowly erode. If it was as efficient as its competitors, it must have charged a monopoly price or it would not have lost its market share. If the U.S. Steel mergers created a firm with higher prices because it was less efficient than its competitors, the conclusions are even more negative. Although economic theory shows that this pricing behavior requires monopoly power, U.S. Steel was judged not to have monopolized in part because its market

share was declining! A similar conclusion might be reached by a court today.

Today, to ascend to a dominant position, a corporation must be more efficient than its competitors. We are protected by the Clayton Act from corporations merging to positions of market power like U.S. Steel. We are not so protected against mergers of agricultural cooperatives. Given the current Capper-Volstead Act interpretation, nothing prevents a cooperative from merging to monopoly, pricing high until its market power dwindles, and merging to monopoly again!

To analyze the costs of the status quo we need to examine how it has worked. By 1967–68, hundreds of mergers and federation/joint ventures had solidified milk cooperative market power. Large monopoly premiums were established by late 1967. About this time some of these coops started to use predatory and exclusionary practices to further their power. One of these practices was pool loading, which USDA watched with increasing alarm. As the intensity of pool loading climaxed in 1971, USDA took action to decrease incentives to load the pools in sixteen affected markets, halting it in some, only decreasing it in others (Masson, pp. 96–102). USDA concern focused on the manipulation of the Orders but was not critical of the prices that resulted (USDA 1976).

In 1972, DOJ filed suit against AMPI, alleging the use of predatory and exclusionary acts and practices. The case was settled by a consent judgment in 1975, and DOJ has been monitoring compliance since then.

What is the evidence that there was market power? Different prices for Class I and Class II commingled milk (i.e., milk with a single cost) require market power. Several studies have shown that milk premiums are significantly related to dominant cooperative market share (Masson, pp. 68–76). Baumer has traced the effect of dominant cooperative market share on the retail price of milk. He finds an effect of 7¢–10¢ per gallon, which far outweighs the impact of supermarket concentration. This power has declined because of antitrust action. The market share premium studies generally lose significance starting with 1975 data, as would be expected if the consent decree had substantially reduced AMPI's market power.[5]

Using the same method we used for regulation, we may estimate the social costs of monopoly pricing. If we assume that all Class I milk had premiums similar to those in reported markets, then we may calculate the effects of this additional price elevation. (We assumed all reported $D^a > \$.05$ was because of market power.) We arrive at additional deadweight losses of \$31 million for 1973. We also calculated that high costs of maintaining market power eroded about three-fourths of AMPI's premium revenue.[6] Some of these costs were due to inefficient transport or other social costs, others were transfers. To be conservative, we assumed that one-quarter of national Class I premium revenue was eroded into social costs. This yielded an additional social cost of \$40 million. The total estimate of \$71 million per annum probably is representative of annual costs from late 1967 to the consent decree of 1975. As the decree reduced AMPI's market power it should have lowered other coops' power as well. AMPI stood in a key area for determining the geographic structure of all milk prices and other coops' market power also came in part from federation with AMPI.

After signing the decree, AMPI started charging a stated premium net of "competitive credits" in its southern region (Fones, Hall, Masson, p. 295, n. 1). We have complete data on actual premiums for only one AMPI southern market. We used a time-series test with Cochran-Orcutt adjustment of the form,

$$D^a = a_0 + a_1 U^m + a_2 PI + a_3 LIII + a_4 T + a_5 F + a_6 C,$$

where $LIII$ is a dummy indicating lifting of Phase III price controls, T is a cost of fuel index, to proxy transport costs, F is an index of dairy feed costs, and C is a dummy variable equal to one after the consent decree. We would hypothesize from the model presented above that $a_1 > 0$, market power increases with the market utilization rate, $a_2 < 0$, Class I price including premium is generally read-

[5] USDA (1976, pp. 53, 63–75) implies that no market power exists unless price exceeds "the cost of alternative supplies." Clearly, such a test can tell only if price exceeds a limit price, not whether the competitive price is the limit price. The USDA authors also cite significant t-values as insignificant by misapplying a two-tailed t-test. Significance declines from over 95% to very low levels after mid-1975 (pp. 66–67). As AMPI lost power, so would other coops, because AMPI was in a key position in the structure of milk prices and a key member of the standby pool. In 1975 the t-values drop for all standby pool member cooperatives (p. 73), and the values for AMPI fall relative to most other coops (Baumer, p. 75).

[6] Because of an arithmetic error, we had stated earlier that virtually all of this revenue was eroded.

justed less frequently than PI, $a_3 > 0$, Phase III seriously limited AMPI's premium charging abilities, $a_4 > 0$, transport cost increases raise market insulation, $a_5 > 0$; as feed costs increase, farmer militancy strengthens bargaining; and $a_6 < 0$, the AMPI consent decree was effective. The results using Cochran-Orcutt adjustments were

$$\begin{aligned} D = -.18 &+ 1.74U^m - .32PI + .82LIII \\ (0.31) &\;\; (3.62) \qquad (5.70) \quad (5.70) \\ &+ .68T + .007F - .53C. \\ &\;\; (1.99) \quad (2.26) \quad (4.47) \end{aligned}$$

(t-values in parentheses)

All t-values except for the constant are significant at the 99% level. C is significant at the 99.9% level.

The AMPI consent decree is working. Given relatively higher utilization rates and transport costs, the predicted premium of the last twelve months of data (into early 1978) was \$.94 without the decree and only \$.42 with the decree. Given a subsequent contempt of court action, higher transport costs, and the establishment of Order 68, these are strong results for less than three years under the decree.

The litigation based on the Sherman Act started about four years after the monopoly was established, and the decree was entered about three years later. Thus, ten years after the monopoly was established, about half its power has been dissipated. This may demonstrate the effectiveness of the Sherman Act given a monopoly; but there need not have been a monopoly, had anticompetitive mergers and joint ventures been limited for cooperatives as for corporations.

Conclusion

Mergers in the late 1960s and early 1970s led to large milk cooperative monopolies. These monopolies have been able to manipulate federal regulation to advantage over competing farmers and regulation continues to protect established power. A social cost analysis model shows that this power cost society at least \$70 million a year prior to antitrust action.

Had cooperative merger been covered by the Clayton Act, this massive degree of power would not have emerged. Without the predatory and exclusionary acts of some coops this power might have been unreachable under the antitrust laws. Without antitrust action, market power would be slowly eroded by monopoly pricing. However, it could be reestablished by use of merger.

Clearly, the antitrust market share standards used to challenge corporate mergers or joint ventures are too stringent for evaluating the anticompetitive impact of cooperative mergers or marketing agreements. But like corporations, cooperatives must be prevented from merger or joint venture where "the effect may be substantially to lessen competition" if society is to be protected from power which far exceeds that originally intended by the Capper-Volstead Act.

An Appraisal of the U.S. Government's Role in Milk Pricing

Paul G. Christ

The U.S. Department of Agriculture administers two major programs that greatly influence the price and other terms of trade for milk and dairy products. These are the Dairy Price Support Program and the Federal Milk Marketing Program. Both originated out of the social distress of the 1930s and have continued in modified form up to the present.

Throughout their history these two programs have been the subject of much professional inquiry and evaluation. Until the early 1970s, the inquiry centered on methods for achieving the perceived goals of the program. Seldom were the goals themselves brought into question.

All that has now changed. I think the change began with the formation in the late 1960s of several massive (by former standards) dairy cooperatives through merger of scores of smaller organizations. These new organizations said and did things that proprietary firms and the general public were unaccustomed to hearing and seeing in the producer-organized sector of the agricultural economy. They boasted of market power. They charged "premium" prices for raw milk. They amassed and spent large political funds. They engaged in allegedly predatory practices. The activities of these organizations gained much public attention, and soon the Cost of Living Council, the Justice Department, the Federal Trade Commission, and consumer groups began focusing on these large dairy cooperatives, their activities, and the institutions under which they operated (see Fones, Hall, Masson, for example). Dairy institutions of all kinds were and continue to be subjected to close scrutiny. Primary among these were the antitrust exemptions provided to cooperatives in the Capper-Volstead Act, the Dairy Price Support Program, and the Federal Milk Marketing Order Program. The questions now go to the foundations of these institutions, more than to the mechanisms employed. Fundamental purposes and goals are being challenged, and clearly the challengers hold the initiative. The topics under consideration at this session illustrate the new thrust of inquiry. One paper deals with the welfare impacts of milk orders and the antitrust immunities for cooperatives, and another deals with the welfare costs caused by regulation of dairy markets. I anticipate that the authors will conclude that the three institutions under consideration have negative welfare impacts. It seems almost trivial to say that nearly all institutions, dairy or not, create market distortions relative to the competitive norm, and thus have negative welfare impacts.

The assignment for this paper is to appraise the government's role in milk pricing. I am not offering a sophisticated technical analysis. Instead, I am offering my evaluation of federal dairy programs from the perspective of a major dairy industry participant. In doing so, I expect to recite much conventional dairy dogma and to run the risk of having my remarks dismissed as tainted or naive. Nevertheless, I think that the pedestrian view of the world merits consideration, and that we, as economic practitioners, must take into account the general level of satisfaction with the institutions we examine.

I plan to proceed with a brief description of federal dairy programs and then comment on specific issues that have arisen in the discussion of their merits.

The Dairy Price Support Program

The Dairy Price Support Program is authorized by the Agricultural Act of 1949 (7 U.S.C. 1466). Under this authority, the Secretary of Agriculture is directed to support the price of milk at a level between 75% to 90% of parity as he "determines necessary in order to assure an adequate supply, reflect changes in the cost of production and assure a level of

Paul G. Christ is the Vice-President for Primary Dairy Processing and Procurement at Land O'Lakes, Inc., Minneapolis, Minnesota.

farm income to maintain productive capacity sufficient to meet future needs." In practice, the Secretary establishes a support price for manufacturing milk only and seeks to achieve that national average price by offering to buy butter, cheddar cheese, and nonfat dry milk at fixed prices. The Secretary does not regulate the prices actually paid by milk processors to dairy farmers. He relies on competitive forces in the manufacturing milk market to insure that processors pay the intended support price, on the average.

The Secretary has been largely successful in achieving the intended level of support. The national average price for manufacturing milk averaged below the support price in only three marketing years between 1949 and 1978 (ASCS, p. 52, ESCS, p. 10).

The administrative discretion of where to set the support price between 75% and 90% of parity is quite wide. It represented 82¢ per hundredweight in 1970 and represents more than $2.00 per hundredweight today. Each year a considerable dispute arises as to the appropriate level of support. Producer groups are suspicious of the anti-inflation talk of recent administrations and have secured from Congress a guarantee of at least 80% of parity through 1981.

A great number of economic considerations enter the deliberations as to the appropriate level of support. Primary among them are the level of government stocks of dairy products relative to disposal opportunities, and the anticipated government costs associated with different levels of support. However, in the final analysis, the decision is political.

Some of the current issues relating to the Dairy Price Support Program are: (*a*) Is there a continuing need to protect the prices and incomes of dairy farmers with a Dairy Price Support Program? (*b*) Is it reasonable to maintain the parity formula for supporting milk prices? (*c*) Does the Price Support Program create unreasonably high milk and dairy product prices?

Continuing Need for the Dairy Price Support Program

Both supply and demand elasticities in the dairy sector are presumed to be inelastic.[1] If we accept this premise, then the industry is subject to wild fluctuations in price to achieve relatively minor changes in quantities produced or consumed. From the producer standpoint at least, this represents an undesirable state of affairs.

Volatile prices bring about more rapid adjustments than do stable prices. However, these adjustments do not come free of cost. Because dairying involves substantial investments in specialized equipment and facilities, supply adjustments are accomplished by abandoning some of the sunk capital. The risk associated with investments in dairying would be higher in a volatile price environment, and fewer producers would engage in milk production.

Some form of price and income protection, then, has the benefit of reducing risk for producers and encouraging a higher level of production at any given price. Consumers benefit from the relative abundance.

Although elementary economic analysis neglects the issue, consumers also express an interest in stable prices. The rapid rises in beef prices in 1973 and 1978–79 could be traced to competitive economic forces, but consumers complained bitterly. Apparently, consumers develop rather stable purchase patterns and resent their disruption by intermittent high prices. The strong public sentiment in favor of price controls administered by the government is another expression of consumer preference for stability.

From a broader public interest view, we could argue that volatile prices are good. The greater the price variation, the more rapidly needed quantity adjustments take place. For milk producers this means "survival of the fittest," and only the most progressive and efficient remain in the industry. It is not clear, however, that the cost savings incurred by weeding out the inefficient would offset the cost of abandoned capital.

Politically, programs that provide price stability seem acceptable to producers and consumers. However, I doubt that both producers and consumers are interested in the same level of price stability. Producers seek a price that will provide competitive returns to resources and a little more, if feasible. Consumers want the lowest price commensurate with abundance.

[1] Gruebele and Babb both accept elasticities of supply of less than 0.14, fluid demand elasticities of less than −.20, and manufactured demand elasticities of less than −.46 in their analyses of federal dairy programs. Their familiarity with the literature is more complete than mine.

We now have the Dairy Price Support Program which certainly has the potential for stabilizing prices, and for stabilizing them at levels that will satisfy either producers or consumers, or neither.

Maximum stability probably can be achieved by setting support prices for milk slightly above expected market-clearing levels. Such a price level would attract a small surplus to be purchased by the government. It also would assure an abundant commercial supply of milk and dairy products, and that short-run supply aberrations would not cause sharp retail price adjustments. While producers might not consider such a support price to be adequate, they would benefit from great price and income security.

It appears that over time the administration of the program has shifted so that it attracts smaller and smaller surpluses. See table 1. The percentage of milkfat and nonfat solids marketings acquired by the government under the Dairy Price Support Program has dropped dramatically from the early 1960s to the late 1970s. I think this change represents a decline in producer influence over the program. There is today much less attention paid to the income needs of dairymen and much more attention given to the level of consumer prices and government costs. Very simply, the political tolerance for a high support price for milk that will satisfy dairymen, but will also drive up consumer prices and government expenditures, is much reduced. For example, government costs under the Dairy Price Support Program reached an all-time high of $714 million in the 1976–77 marketing year, and there was much concern about the need, reasonableness, and justification for such an expensive program. However, if the 1962 volume of purchases were valued at the 1 April 1977 purchase prices, the cost would have been more than double the actual 1976–77 costs.

Table 1. Percentage of National Marketings of Milkfat and Nonfat Solids from the Commercial Market by Programs of the U.S. Department of Agriculture during Five-Year Periods, 1949–68

	USDA Removals as a Percentage of Marketings	
5-Year Period	Milkfat	Nonfat Solids
1949–53	2.76	3.84
1954–58	5.28	8.76
1959–63	5.70	11.18
1964–68	4.68	7.92
1969–73	4.62	3.66
1974–78	2.38	3.28

Source: *Dairy Situation*, DS-374, p. 24.

I see a danger in this trend toward administering the program in a manner intended to minimize short-run consumer price impacts and government expenditures. Such a course of action would be tantamount to abandoning the program and the worthy goals of "stability," "adequate supply," and "reasonable prices." I would state emphatically that we have a continuing need for the Dairy Price Support Program to retain the productive capacity of the dairy industry and to gain maximum assurance of an abundance of milk and dairy products at stable prices.

Should the Parity Formula Be Retained?

The parity index has been the primary adjustment factor in calculating the support price for milk. This aspect of the Dairy Price Support Program is under attack and alternatives have been proposed (Special Dairy Policy Advisory Committee, pp. 32–46). The basic arguments against the parity index are that it is out-of-date, that it is not responsive to the cost experience of dairy farmers, and that it is out of harmony with the methods used to support the prices of feed grains, food grains, and soybeans.

The basis of the parity index is old. It was created in the 1930s using data from 1910–14. It accurately reflects changes in specific input prices, but it does not take into account changes in technology, improved productivity, or increased scale of operation in American agriculture. I do not think it matters if the index has a long history. It does reflect the long-run movement of input and consumer prices, and thus does reflect a large component of the economic environment faced by farmers. It tracks the general price level reasonably well. Compared to the alternatives of a dairy-specific parity index or a cost of production index, the parity index is more stable.

The parity index does not determine the support price for milk. It is the mover that determines the bounds of the administrative decision as to where to set the support price for milk. The alternatives—the dairy-specific parity index, which would weight input prices in proportion to their use in the dairy enter-

prise, and the cost-of-production index—would serve the same purpose. They would simply establish the bounds for administrative discretion, and would not set any prices.

Changes in technology, input mix, productivity, and scale of operation do not argue against the parity index. They simply say that a lower percentage of parity in the present would provide the same net income for agriculture that a higher percentage of parity would have provided in the past. Offsetting this argument for income support at a lower percentage of parity is the increasing income needs of farmers to retain comparative standards of living relative to the nonfarm sector.

The question should not be "Is the parity formula appropriate?" Rather, it should be, "What percentage of parity is appropriate?"

I see little relevance in the argument for harmonizing the price support calculations for milk with the price support calculations for other commodities. The real issues are workability and acceptability. Variations in the supply of milk are much smaller than variations in the supply of field crops. Thus, a simple price support and purchase program may work well for milk, but not for food and feed grains. The greater the variations in supply that are not responsive to price, the greater the complexity of managing the supply in a way that stabilizes prices and incomes for producers.

The actual price at which commodities are supported is a political decision within the range of flexibility provided by law. It matters little whether the price target is to be achieved through government offers to purchase or through deficiency payments. What does matter is the cost and complexity experienced by the government by doing it one way or another. In the case of milk, there is an extra administrative burden associated with purchasing, storing, and disposing of dairy products, but government costs are small compared to a deficiency payment program.

It is not exactly correct that target prices are based on cost of production, and thus offer greater protection for producers. In the long run, target prices are set at levels that will keep government costs within acceptable bounds. It may be politically convenient at times to relate target prices to cost of production, but there is no iron rule tying the two together.

I believe the arguments for substituting an alternative mover for the parity index is a subterfuge to expand downward the range in which the support price can be set, opening the opportunity for lower support prices. The Special Dairy Policy Advisory Committee estimates lower milk prices through 1981 using either alternative to the parity index.

Expanding downward the range within which the support price may be set administratively will not assure a lower support price. If the goals of price stability and supply adequacy are pursued equally under the three alternatives, the result should be the same, except that greater inherent volatility would be introduced by the dairy-specific parity index or the cost-of-production index.

I see no need nor any desirability for abandoning the present dairy price support calculation using the parity index as a mover. If the support price attracts unacceptable surpluses of dairy products, it is a problem resulting from the administrative choices made within the range of flexibility provided, and not a problem resulting from the use of the parity index as part of the calculation.

Does the Dairy Price Support Program Enhance Consumer Prices?

The trivial, short-run answer to this question is, yes. Any time the government purchases dairy products at the support purchase price, it means that the commercial market will not clear at those prices. Wholesale and retail prices for dairy products would be lower if the government suddenly withdrew from the market.

Gruebele estimates that "During 1950–1975, the elimination of the price support program for dairy products would have been likely to reduce the average price for milk by 7 percent and milk production by 1.8 percent. If price supports were removed, milk prices probably would be 2.8 percent lower and production 0.8 percent lower between 1976 and 1980 than with price supports" (Gruebele, p. 30).

The long-run question is more difficult. Without a price-stabilizing, price-support program, the economic risk of milk production would increase, leading to reduced milk production at any given price. Also, the increased volatility of consumer prices might alter consumption patterns in unpredictable ways.

It is an unavoidable consequence of a price support program designed to increase price stability that at some times commercial prices will be above market clearing levels. If there is

to be a program with any effect, then it will have short-run, price-enhancing effects. The degree of price enhancement is produced not by the existence of the program, but by the administrative choices made within the available range of flexibility. For example, the price-enhancing effects of the Dairy Price Support Program probably would have been less if the support price had been fixed at a lower level of support in the past.

In the future, we can choose the amount of price enhancement provided by the Dairy Price Support Program. I do not think it will be great. Producer arguments for price and income enhancement are likely to be overridden by concerns about inflation and the status of the federal budget.

Federal Milk-Marketing Order Program

Federal milk-marketing orders are authorized by the Agricultural Marketing Agreement Act of 1937, but trace their origin to the Agricultural Adjustment Act of 1933. The objectives of Congress were to "establish, as the prices to farmers, parity prices . . . protect the interest of consumers by . . . gradual correction of . . . current prices," and to "establish and maintain such orderly marketing conditions . . . as will provide, in the interests of producers and consumers, an orderly flow of the supply . . . to avoid unreasonable fluctuations in supplies and prices." (7 U.S.C. 602).

Federal milk-marketing orders regulate milk handlers disposing of packaged fluid milk products within specifically defined geographic areas. There are forty-seven milk-marketing orders now in effect, although at one time there were eighty-two. However, the scope of regulation has expanded to the point where 80% of U.S. Grade A milk marketings are regulated under federal milk-marketing orders.

The fundamental structures of federal milk-marketing orders are (*a*) classification of milk according to use, (*b*) establishment of uniform minimum prices for milk used in each class, (*c*) a method of distributing the proceeds for milk in all uses to producers and associations of producers.

Federal milk orders and amendments are adopted following a long administrative procedure, and approval by the milk producers who are affected by the order. The most important part of the administrative process is the public hearing at which interested parties offer facts and arguments for or against specific proposal. In the past, most disputes over federal milk orders and their provisions were resolved through the hearing process. In recent years we see a greater political challenge to the order system than we have had in the past and less reliance on the administrative wisdom of the Secretary of Agriculture.

Current issues with respect to federal milk-marketing orders include (*a*) Is classified pricing necessary? (*b*) Are Class I prices too high? (*c*) Are Class I prices too low? (*d*) Do federal milk orders enhance the market power of dairy cooperatives?

Is Classified Pricing Necessary?

The Agricultural Marketing Agreement Act of 1937 directs that federal milk orders provide for the "classifying [of] milk in accordance with the form in which or the purpose for which it is used, and fixing, or providing a method for fixing, minimum prices for each such use classification which all handlers shall pay . . ." [7 U.S.C. 608c (5) (A)].

Most orders provide for three classes of use. Class I milk is that milk disposed of as packaged fluid milk products. Class II milk is milk disposed of as packaged fluid cream or used to produce cottage cheese, frozen desserts, and a variety of "soft" manufactured dairy products. Class III milk is milk used to produce "hard" manufactured dairy products such as cheese, butter, and dry milk products.

Prices for all three classes of use are established on the basis of the Minnesota-Wisconsin manufacturing milk price. The Class I price is the Minnesota-Wisconsin price for the second preceding month, plus a Class I differential. The differential ranges from a low of $1.12 at Minneapolis under the Upper Midwest order to a high of $3.15 at Miami under the Southeastern Florida order. The Class II price is the Minnesota-Wisconsin price, plus 10¢, and the Class III price is the Minnesota-Wisconsin price for the month.

Classified pricing means different prices for different uses or "markets" for milk. Some see classified pricing as a form of price discrimination designed to increase average revenue above the competitive norm (Masson, Masson, Harris). It is argued that such price discrimination results in high social cost and large transfers of income from consumers to producers.

Classified pricing does not conform to the competitive norm. Neither does the oligopsonistic form of market organization that characterized many fluid milk markets prior to the adoption of federal milk markets. It is probable that the price-enhancing effects of classified pricing brought producer prices closer to the competitive norm than before. I believe that classified pricing is a useful device that helps insure the smooth functioning of the fluid milk market, and that consumers need for fluid milk could not be met without classified pricing.

It costs more to produce Grade A milk, which must meet strict production and sanitation requirements, than it does to produce manufacturing milk. Therefore, Grade A dairy farmers must be paid a higher price than manufacturing milk producers in order to maintain adequate Grade A production.

If all Grade A milk could be bottled and sold in fluid form, one price for Grade A milk would solve the problem. But not all Grade A milk can find a Class I or fluid market outlet. Milk production is reasonably steady on a day-to-day basis, but varies widely on a seasonal basis. The variations in demand are far out of harmony with the variations in milk production. Fresh fluid milk cannot be stored long enough to cover these variations, so if sufficient Grade A milk is available on the day and in the season when the demand for fluid milk is greatest, then too much Grade A milk will be available at all other times.

What happens to this extra or "reserve" Grade A milk if it is not needed for bottling? It is processed into manufactured dairy products that compete on even terms with similar products made from manufacturing grade milk. A milk manufacturer could not accept reserve Grade A milk for processing if the price is higher than his competitors pay for manufacturing grade milk. So it is apparent that the supply of Grade A milk cannot clear the market at a price higher than the value of manufacturing milk. But if greater returns are needed to maintain a steady supply of Grade A milk, then there is only one way to get those returns, and that is through a differentiated Class I price that is high enough to compensate farmers for both the extra costs of producing Grade A milk, and for the losses they incur in disposing of reserve supplies in the manufacturing milk market.

Classified pricing is necessary to get Grade A milk produced on the farm. Classified pricing is also necessary to get the Grade A milk moved from the farm to the consuming center. A plant operator receiving milk in the country has the choice of processing the milk on the premises and paying the Class III price for it, or of shipping the milk to a consuming center and paying the Class I price. Clearly, he will not choose to ship unless the Class I price at the consuming center covers his local Class I cost plus the hauling cost. Milk is expensive to haul because it is bulky and perishable and must be transported in temperature-controlled, sanitary equipment.

The high cost of moving milk accounts for most of the variation in Class I prices around the nation. Milk must move out of the upper Midwest to satisfy the needs of consumers in the South and East. A difference in Class I prices is necessary to pay the freight.

I believe that the Grade A milk-marketing system cannot operate satisfactorily without classified pricing. A dependable supply of Grade A would not be produced; the Grade A market would not clear reserve supplies; and fluid milk would not move from production areas to consuming centers.

Are Class I Prices Too High?

If classified pricing is necessary to attract Grade A milk to fluid markets, how high should Class I prices be to accomplish this purpose? There is no clear-cut answer, but several analysts argue that the present structure of Class I prices is higher than necessary to attract an adequate supply (see Dobson and Buxton, for example).

The most difficult aspect of this issue is the definition of an "adequate" supply. Adequate supply for a fluid milk market requires that sufficient Grade A milk be available to meet fluid demand at all times. A reserve supply of Grade A milk is necessary to cover the variations in production and processing demand. In addition, not all the Grade A milk received at a bottling plant can be used as Class I milk because of plant loss, inventory variation, route returns, and the fact that the fat test of finished products is lower than the fat test of producer milk.

How much "reserve" Grade A milk is needed to cover all these variations? Conventional wisdom has held that a 20% annual reserve should be adequate. USDA adopted this figure in its 1964 decision (29 F.R. 9110-9125)

implementing the changes required by the Supreme Court in the Lehigh decision (*Lehigh Valley Cooperative Farms, Inc. et al.* vs. *United States et al.*, 4 June 1962), and it carries forward in the present provisions of federal milk orders.

Dobson and Buxton used a more sophisticated approach and adopted a 37% reserve allowance in their analysis (Dobson and Buxton, p. 9). This included an allowance of 12% to cover seasonal variations plus 25% to cover variations in daily demand as well as unavoidable Class II and Class III uses in bottling plants. I believe these estimates are reasonable if viewed as minimum operating reserves in a highly coordinated system of markets.

There is a further justification for maintaining a reserve of Grade A milk in federal milk order pools over and above operating requirements. This is the need to maintain blend price alignment among markets. The so-called "blend" price is the weighted average of the class prices in a federal order market and is the minimum price to be paid producers and associations of producers.

The basic supply of producer milk associated with any federal order market is attracted to it by the blend price. Producer milk can be transported from the farm to markets as much as 500 miles away, so dairymen and their marketing associations have a wide range of choice as to which federal order pool to participate in. Their logical choice is the pool rendering the highest blend price, net of transportation costs. Less milk will be pooled in a market with a relatively low farm-point blend price and more milk will be pooled in a market with a relatively high farm-point blend price. The natural result of producers shifting to more attractive markets will be a structure of blend prices that reflect differences in transportation costs from production areas to consuming centers.

To achieve a price structure of this sort, there must be differences in the percentage of producer milk used in Class I, as well as differences in Class I prices. For example, consider the blend price relationship that should exist between Minneapolis and Kansas City if producer milk is to flow from the former to the latter. The two cities are about 450 miles apart. If transportation costs are 15¢ per hundredweight per hundred miles, then the blend prices in the two markets should differ by 67.5¢ (15¢ × 4.5). In 1978, the Class I price averaged $11.03 per hundredweight in Kansas City and $10.43 in Minneapolis. The blend price in Kansas City averaged $10.38 in 1978, so a properly aligned blend price for Minneapolis would be $9.705 ($10.38–$.675). To achieve that blend price in Minneapolis, the upper Midwest market should experience no more than a 13% Class I utilization. Thus, the reserve requirement for the upper Midwest market amounts to 87%.

Following this analysis, reserve requirements for the upper Midwest market reach infinity if transportation costs exceed 18¢ per hundredweight. Transportation costs do exceed 18¢ per hundredweight, so an alternative to associating an infinite quantity of Grade A milk with the upper Midwest market is to increase effective Class I and blend prices in Kansas City and other markets outside the upper Midwest. This has been accomplished to some degree through the bargaining activities of dairy cooperatives.

The important point is that reserve requirements needed to achieve a workable blend price structure for a system of markets can easily exceed the reserve required to cover variations in milk supply and fluid demand. This leaves open the question of whether existing Class I prices are higher than necessary to attract an adequate supply. I doubt that they are.

Are Class I Prices Too Low?

We can suspect from the previous discussion that Class I prices may be too low to attract sufficient milk to align properly blend prices. Higher Class I prices and higher utilization of producer milk in Class I in markets outside the upper Midwest would facilitate improved blend price alignment, and reduce the necessity of associating increased volumes of Grade A milk with the system of federal order pools.

While relative blend prices are important in determining which producer milk is associated with which federal order pools, relative Class I prices largely determine the movement of plant milk between federal order markets. Under present provisions, a load of milk transferred from one federal order market to another is classified on the basis of the utilization of the receiving plant or the receiving market, whichever represents the lower Class I use. The consequence of this provision is that only part of the load of milk is assigned to Class I, and the remainder is assigned to Class III or Class II. Class II and Class III prices are the

same in most federal order markets, so there is no price difference to compensate for the cost of transportation. There is normally a difference in Class I prices to compensate in part for the cost of transporting milk between two markets.

If Class I prices are to be aligned to encourage the movement of plant milk from low utilization markets to high utilization markets, then the difference in Class I prices must exceed the cost of transportation. For example, if milk is to be shipped from a low price market to a high price market with an 80% Class I utilization, then the Class I price difference should be 125% of the hauling cost. Hauling costs are incurred on 100% of the load, while the difference in Class I prices is paid on only 80% of the load.

Consider the magnitude of Class I price changes needed to facilitate the inter-order movement of plant milk with the present transfer provisions. During 1978, Class I utilization in the Kansas City market reached a peak for the year in November at 63%. With a hauling cost of 25¢ per hundredweight per hundred miles, a Class I price difference of $1.79 would be necessary to move plant milk from Minneapolis to Kansas City (450 miles × $.0025 hauling cost per mile ÷ 63% Class I utilization). The actual difference in Class I prices is only 62¢, so a Class I price increase of $1.17 may be in order for Kansas City. With the same hauling cost, a Class I price difference of $3.50 would be required to move plant milk from Chicago to Miami in June 1978 (1,329 miles × $.0025 hauling cost per mile ÷ 95% Class I utilization). The actual Class I price difference is only $1.89, so an argument can be made for increasing the Miami Class I price by $1.61.

Fortunately, increasing Class I prices is not the only alternative for facilitating the movement of plant milk between markets. It is possible to adopt different transfer and allocation provisions and it is possible to provide compensation for hauling costs directly out of federal order pool funds.

My conclusion is that Class I prices probably are too low. There is a need to increase total federal order revenue to attract sufficient Grade A milk to achieve blend price alignment, and there may be a need to increase Class I price differences between markets to facilitate the movement of plant milk to high utilization markets.

Do Federal Milk Orders Enhance the Market Power of Dairy Cooperatives?

One of the alleged evils of federal milk-marketing orders is their use by dairy cooperatives to exercise market power. The fact that dairy cooperatives sell milk in most markets at prices that exceed the federal order minimums is taken as conclusive evidence of market power.

I have already argued that federal order prices are inadequate to allocate properly producer milk among markets or to facilitate the movement of plant milk to high utilization markets. In spite of this inadequacy, the national milk-marketing system seems to function reasonably well. What is not generally recognized outside the dairy industry is that it is the prices charged by dairy cooperatives, and not the federal order minimum prices, that provide the incentives to make the system operate efficiently. A reasonable argument can be made that federal order prices should be modified to provide all the incentive needed, but few, if any, antagonists advance this view. Babb, Bessler, and Pheasant examined, in a recent report, over-order prices charged by dairy cooperatives. They conclude that the relationships between over-order prices and "cooperative and processor concentration were generally not statistically significant . . . [and the impact of these variables] . . . on over-order payments was small. Measures of price relationships among orders were significant and accounted for much of the variation is over-order payments" (Babb, Bessler, Pheasant, p.i). The forces that support over-order prices may in fact be economic rather than structural.

If we define market power as the ability to influence the terms of trade in market transactions, then dairy cooperatives do, indeed, exercise it. Their ability to create appropriate incentives for the production of milk and its reasonable allocation among markets indicates they are able to influence buyers to accept terms that go beyond Federal order minimums. Maybe those terms are not unreasonable in terms of competitive market forces, but they do represent more than could normally be achieved in an oligopsonistic market.

Whatever market power dairy cooperatives do possess, I think, derives mostly from the existence of federal milk orders and not much from size or concentration of sellers. The real

source of market power is the ability of the seller to deny a supply to the buyer. It is obvious that if a buyer can get an alternative supply on his own terms, the seller can exercise little market power. In unregulated milk markets, efforts to deny a supply to concentrated buyers through strikes and diversions are doomed to fail. The sellers who are individual dairy farmers, whether organized or not, suffer immediate and great economic distress and soon lose their resolve. To be successful, dairymen must find a way to maintain incomes while denying a supply to the buyer. Federal orders provide limited means for accomplishing this goal.

Liberal pooling provisions in the Chicago Regional and upper Midwest markets permit cooperatives to qualify for the blend price while diverting most or all of their milk to manufacturing outlets, instead of delivering it to a resistant fluid milk processor. The processor is faced with the choice of accepting the cooperative terms or securing an independent supply from individual dairy farmers. Securing an independent supply is an expensive alternative, because the buyer must pay prices to farmers in excess of the cooperative pay price, provide field service, coordinate trucking, control quality, payroll producers, and find facilities for disposing of reserve milk. However the opportunity for the buyer to seek an independent supply places an upper limit on the favorable terms of trade a cooperative can extract from a buyer.

The liberal pooling provisions in the Chicago and upper Midwest markets help cooperatives to charge limited over-order prices in those areas, and transportation costs permit these improved terms to be extended throughout the federal order system.

I believe federal milk orders do enhance the market power of cooperatives, but that market power is severely limited by the open opportunity for the buyer to secure an independent milk supply.

Conclusion

In evaluating the government's role in milk pricing, I see little cause for alarm. The Dairy Price Support Program provides the means for stabilizing dairy markets to the benefit of producers and consumers. The degree to which it achieves this purpose depends on administrative choices rather than on the mechanical aspects of the program. I believe an enlightened policy for the future would be to maintain intact the present program and set the support price for milk at a level that will attract a small surplus.

Issues related to the federal milk order program are more complex. While classified pricing is a necessary component in a smoothly functioning national market for fluid milk, considerable reexamination of price levels and price relationships is in order. The hearing process is appropriate and readily available to accomplish this reexamination.

Concern about the relationship of dairy cooperative market power and federal milk marketing orders is undue. Cooperatives do exercise limited market power under milk orders, but they seem to use that power to extract competitive returns, and little more.

Welfare Costs and Interregional Income Transfers Due to Regulation of Dairy Markets

Roger A. Dahlgran

The U.S. dairy industry is claimed to be unique in that it is subject to more regulation than any other agricultural industry (Hallberg and Fallert, p. 3). Whether the dairy industry is subject to more or less regulation than any other particular agricultural industry is not important. For our purposes, it is sufficient only to agree that the dairy industry is highly regulated. It is the purpose of this paper to formulate a model and estimate the interregional transfers and welfare losses created by the current regulatory structure imposed on U.S. dairy markets.

Given the degree of dairy market regulation, it would be useful to summarize the regulation that is unique to dairying. Sanitary grading was established by regulation to differentiate raw milk by its quality or condition of production. Grade A milk is produced under the strictest sanitary conditions and is eligible for fluid, or beverage, consumption. Grade B milk is produced under less strict sanitary conditions and is eligible only to be incorporated into manufactured dairy products such as cheese and butter.

Classified pricing and pooling provisions affect only grade A milk and are established by federal and/or state regulatory agencies. Classified pricing is the practice of establishing different minimum prices for raw grade A milk depending on how the milk is utilized. Grade A milk going into fluid (beverage) utilization receives the higher class I price, while grade A milk going into manufacturing utilization receives a lower class II or class III price. The class I price is typically established as the class III price plus a fixed differential.[1] Pooling is the practice of distributing the proceeds of grade A sales so that all grade A producers shipping milk into the pool receive the same or average price.

The U.S. dairy industry is also subject to a price support program which is based on the concept of parity (Hallberg and Fallert, p. 11). The price of raw milk is supported by USDA purchases of manufactured dairy products. This support of wholesale butter, cheese, and nonfat dry milk prices is transmitted back to the farm level as higher raw milk prices. In order for price supports to be effective in the United States, import restrictions have been established so the USDA can support domestic dairy prices and producers' incomes without having to support world dairy prices as well.

A final set of regulations that indirectly act upon the dairy industry consists of those that affect cooperatives. Seventy-five percent of all milk marketed in the United States is marketed through dairy farmers' coops (Jacobson, p. 171). Any regulation affecting dairy coops thus affects the structure of milk markets.

Literature Review

Ippolito and Masson formulated a national model of the U.S. dairy industry as shown in figure 1. U.S. aggregate functions are shown as *DF*, the derived demand function at the farm level for milk for fluid utilization; *SA*, the supply function for grade A milk; *AR*, the average revenue or grade A blend price function due to pooling; *DM*, the derived demand function at the farm level for milk for manufacturing utilization; *SB*, the supply function for grade B milk, assumed to be produced mainly in the Minnesota-Wisconsin area; and *DII*, the

Comments from and discussion with Richard A. King are gratefully acknowledged.

[1] The class II price is usually $0.10/cwt over the class III price. Henceforth, class II and class III utilization will both be subsumed under class II utilization.

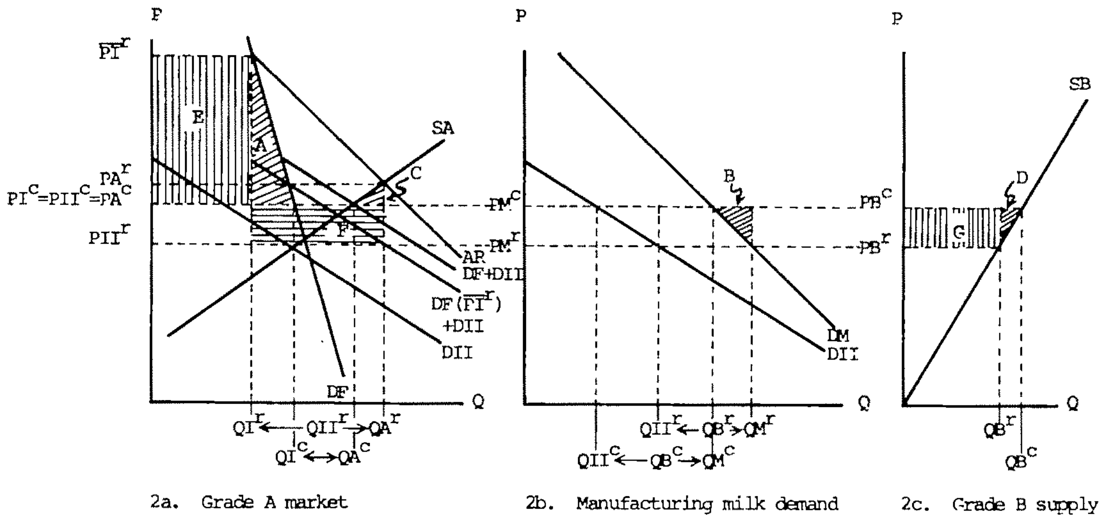

Figure 1. The Ippolito and Masson model of the U.S. dairy industry

demand for class II milk, i.e., demand for manufacturing milk net of grade B supplies. In the absence of classified pricing, the demand for grade A milk would be equal to $DF + DII$. In this case, the competitive solution would be the price-quantity vector,

$$(PI^c, PII^c, PA^c, QA^c, QI^c, QII^c, PM^c, QM^c, PB^c, QB^c).$$

With classified pricing, the minimum class I price $\overline{PI^r}$ is set administratively and results in a solution price-quantity vector,

$$(\overline{PI^r}, PII^r, PA^r, QA^r, QI^r, QII^r, PM^r, QM^r, PB^r, QB^r).$$

The welfare costs of classified pricing and pooling are shown as area A, the lost consumer surplus due to underconsumption of fluid milk; area B, the resource cost due to greater than optimal consumption of manufactured dairy products; area C, the resource cost due to overproduction of grade A milk; and area D, the resource cost due to underproduction of grade B milk. The transfers implicit in this model are area E, the transfers from fluid milk consumers to grade A milk producers; area F, a subsidy from grade A milk producers to manufactured product consumers; and area G, the transfers from grade B milk producers to manufactured product consumers. This model is a generalization of Kessel's earlier grade A model which displayed deadweight losses due to underconsumption of fluid milk, deadweight losses due to overproduction of grade A milk and transfers from fluid milk consumers to grade A milk producers.

Blakley and Riley (1974, p. 1, 1975) point out that when policy changes are under consideration, trade-offs between groups or regions may be much larger than all aggregate changes averaged over all groups. Their two studies examined the effect of alternative class I pricing policies on grade A milk markets in the United States.

The Ippolito and Masson model provides a good base for examining the magnitude of welfare costs and transfers but it does have some shortcomings. One shortcoming of the Ippolito and Masson model is, as Blakley and Riley point out, regional gains and losses may be large relative to the aggregate quantities. A second problem with the Ippolito and Masson model is the assumption of a competitive price surface. In their analysis Ippolito and Masson assumed that the Minnesota-Wisconsin area would be the only surplus producing region in the country. Subsequent analysis by Fallert and Buxton, and Hallberg et al. suggests that there would be three surplus producing regions in an unregulated environment. Another criticism of all models that indiscriminately use elasticity estimates derived from previous studies is that elasticity estimates from models that ignore the effect of regulation may be seriously biased (Prato, p. 221). A fourth criticism is not directed toward Ippolito and Masson's work but is directed toward models that assume that in competitive equilibrium the price of grade A milk will equal the price of grade B milk. This assumption is unrealistic as long as there is a cost of production differential between grade A and grade B milk produc-

tion. A final problem of measuring the welfare cost of regulation is the exclusion of risk considerations on the part of producers.[2]

Mathematical Model of a U. S. Dairy Market

On the demand side, milk is demanded at the farm level for one of two purposes; it is either bottled and sold as beverage milk or it is incorporated into manufactured dairy products. As such, there exist two demand functions for raw milk, fluid demand and manufacturing demand. Demand functions at the farm level are generally specified as[3]

$$(1)\quad QF = QF\,(PF, Inc, Pop, \mathbf{d}, t, Org, EF),$$
$$(2)\quad QM = QM\,(PM, Qs, Inc, Pop, \mathbf{d}, t, Org, EM),$$

where QF is the quantity of fluid milk demanded per day; QM is the quantity of manufacturing milk demanded per day; PF, price paid per hundredweight for milk for fluid utilization; PM, price paid per hundredweight for milk for manufacturing utilization; Inc, per capita income; Pop, population of the market; Qs, USDA price support purchases (net removals); **d**, vector of discrete monthly dummy variables to account for environmental and institutional changes over the year; t, trend variable to account for linear changes in the age distribution of the population and for linear changes in prices not included in the model; Org, discrete variable to account for market reorganizations and mergers; EF, EM, errors of estimation for the respective demand functions.

Farmers supply only two types of milk, either grade A milk or grade B milk. Mathematical optimization of the producers' profit functions subject to the industry production functions for grade A and grade B milk indicates a general formulation of the supply functions as

$$(3)\quad QA' = QA'(PA, PB, Pfd, Phy, Pcw, Pwg, Pin, \mathbf{d}, Org, EA),$$
$$(4)\quad QB' = QB'(PA, PB, Pfd, Phy, Pcw, Pwg, Pin, \mathbf{d}, Org, EB),$$

where QA' is the desired production of grade A milk per day; QB' is the desired production of grade B milk per day; PA, price per hundredweight received by farmers for grade A milk; PB, price per hundredweight received by farmers for grade B milk; Pfd, price per hundredweight paid by farmers for dairy feed; Phy, price per ton received by farmers for all hay; Pcw, price per hundredweight received by farmers for cull dairy cows; Pwg, wages paid by farmers for farm labor; Pin, interest rate on three- to five-year government bonds; EA, EB, errors of estimation for the respective supply functions.

The relationship between the actual quantity supplied and the desired quantity supplied can be specified by a linear partial adjustment model

$$(5)\quad QA_t - QA_{t-1} = a^*\,(QA'_t - QA_{t-1}) + UA,$$
$$(6)\quad QB_t - QB_{t-1} = b^*\,(QB'_t - QB_{t-1}) + UB,$$

where QA', QB' are defined above; QA, actual output of grade A milk per day; QB, actual output of grade B milk per day; a^*, b^*, respective coefficients of adjustment for grade A and grade B milk production; UA, UB, errors of estimation for the respective adjustment functions.

These supply models are interdependent in that both the grade A and grade B supply functions contain PA and PB. A great deal of multicollinearity is expected to exist between the grade A and grade B milk prices. The effect of this multicollinearity is minimized by referring to the assumption of constrained profit maximization. When this is done, a symmetry restriction emerges which specifies that either

$$(7)\quad \partial QA'/\partial PB = \partial QB'/\partial PA, \text{ or}$$
$$(8)\quad E_{QA',PB} \times PA \times QA' = E_{QB',PA} \times PB \times QB'$$

be imposed as a restriction during the estimation of the model where $E_{y,x}$ is the elasticity of y with respect to x. Normally, it is preferable to have estimates of elasticities by using double-logarithmic models. The restriction (8) associated with these supply models dictates that the estimation of price slopes is to be preferred to the estimation of elasticities since restriction (8) implies a nonlinear model.

The identities associated with this dairy market model are first, total supplies to the market are equal to total demands. Therefore,

$$(9)\qquad QA + QB = QF + QM.$$

Second, grade A farmers will receive the grade A price,

[2] If milk producers are risk-averse and regulation reduces the variance of milk prices, then the supply function will shift out as a result of regulation. More will be said about this later.

[3] These general functions may be specified as either linear or log-linear functions.

$$(10) \quad PA = [PF \times QF + PM \times (QA - QF)]/QA.$$

Third, the price paid by processors for milk for fluid utilization is the minimum class I price[4]

$$(11) \quad PF = PI.$$

And finally, all milk going into manufacturing utilization receives the same price regardless of its eligibility, so

$$(12) \quad PII = PM = PB.$$

Empirical Investigation

Since this effort is concerned with welfare costs within markets and transfers within and between markets, estimation must be performed on individual markets. At the end of 1976, fifty federal order markets and seventeen state order markets encompassed 100% of regulated milk deliveries, 97.5% of grade A milk deliveries and 79.0% of all milk deliveries. One possible approach to measuring the desired transfers and welfare losses would be to fit price and quantity data for each of these sixty-seven markets. The time required to collect and analyze the data dictated that a sampling approach be used to draw inferences about the larger population of markets. The ten largest milk markets in the United States in 1976 accounted for two-thirds of total milk deliveries and were included in the sample. Six markets from the set of fifty-seven relatively small markets were drawn at random, subject to geographic stratification. The sixteen markets included in the original sample are listed in table 1.

Several modifications were made to the original sample. The California state order market was excluded from estimation because California has a five class system of classified pricing and a complex and restrictive base plan (Milligan). The model constructed would not provide reliable elasticity estimates of supply and demand parameters in California. Second, North Carolina was included in the sample with unit probability due to the low cost of obtaining data. Finally, the Maine market was excluded due to nonresponse in data collection.

Estimation was performed using monthly time-series data from 1968–77 for the fourteen markets. All quantities were converted to per day flows to correct for different length months while all prices were deflated by the consumer price index. Not all 120 observations were used for every market as market reorganizations with few observations on the reorganized market sometimes resulted in unrealistic elasticity estimates. Table 1 lists a summary of elasticity estimates by market.

The purpose of sampling subject to geographic stratification was to measure possible regional and market size effects on elasticities of the form

$$(13) \quad E_{Q,P} = \mu + \rho_i + \sigma_j + \epsilon_{ij},$$

where $E_{Q,P}$ is a general elasticity of some quantity Q with respect to some price P, ρ_i is the effect of regional strata i, σ_j is the effect of size strata j, and ϵ_{ij} is the error of measurement. By use of least squares, $\hat{\mu}$, $\hat{\rho}_i$, and $\hat{\sigma}_j$ were estimated and these values were then used to generate a set of predicted values for $E_{Q,P}$ for all markets not in the sample. The least-squares procedure generally provided a poor description of the elasticities estimated in the sampling step as none of the t-values for $\hat{\rho}_i$ and $\hat{\sigma}_j$ were significant at the 0.10 probability level. Also, the predicted values generated by the regression model were frequently of the wrong sign. Given the insignificance of the size and regional effects, these effects were assumed to be zero and a value for each elasticity was found that is uniform across all markets. The value chosen was the mean of all the parameter estimates after severe outliers had been deleted. The resulting estimates are given at the bottom of table 1 and were assumed to apply to all markets both within and outside the sample.

Computation of the welfare costs and interregional transfers resulting from regulation requires a model of unregulated equilibrium. To model the United States dairy industry in the absence of regulation, a reactive programming model was developed using 1976 milk-marketing and utilization data. Sixty-seven fluid markets corresponding to the state and federal order markets and seventy-five manufacturing markets were identified in terms of prices, quantities, and geographical coordinates. Supply areas were assigned geographically as states and likewise were identified by prices,

[4] The actual price paid for fluid milk is frequently the federal order minimum plus an over-order premium. This over-order premium reflects the cost of services performed by cooperatives, the cost of obtaining alternative supplies, and any supracompetitive premium. The assumption of the constancy and independence of this over-order premium and the error of the fluid equation was utilized. The class I minimum price was then a proxy for PF.

Table 1. Summarization of Estimated Policy Elasticities

[c] Only positive estimates are included in the calculation of the mean.

quantities, and geographical coordinates. Both the supply and the demand areas were then aggregated into regions. Distances between supply and demand regions were computed (see Tramel and Seale) and converted to transportation costs using the formula given by Lough (p. 18). Manufacturing milk transportation costs were computed as the cost of shipping the fluid milk equivalent in manufactured products and were computed to hold the same proportional relationship to fluid transportation costs as in Hallberg et al. Fluid and manufacturing demand regions were assumed to have an elasticity of demand equal to -0.112 and -0.352, respectively. Since grade A and grade B production are interdependent, it was assumed that in an unregulated environment the fall in the grade A price and the rise in the grade B price would cause grade A producers to convert to grade B production until the cost of production differential was attained and total manufacturing demand was supplied out of grade B production. In terms of the modeling effort, this assumption was incorporated by using a total supply function and the assumption that, in unregulated equilibrium, the grade B price would be below the grade A price by the cost of production differential, $0.15 per hundredweight [Ippolito and Masson (citing Bartlett), p. 37]. The elasticity of the total supply function was specified with respect to the grade A price since there is a one-to-one correspondence between the grade A price and the grade B price in unregulated equilibrium. Specifically, since

$$(14) \qquad QT = QA + QB, \text{ then}$$

$$(15) \qquad E_{QT,\,PA} = \frac{QA}{QT} E_{QA,\,PA} + \frac{QB}{QT} E_{QB,\,PA} = 1.19,$$

which was the assumed elasticity of total milk supplies with respect to the grade A price.[5]

In order to have grade B prices the required $0.15 per hundredweight below grade A prices in the final solution, manufacturing demand was inflated by 1.5% to give manufacturing demand in terms of the grade A price. When the solution was obtained, the manufacturing demand function, which was formulated in terms of the grade A price, corresponded to the true manufacturing demand function, which was formulated in terms of the grade B price. The difference between these manufacturing demand functions was the required $0.15 per hundredweight. The reactive program was initialized at the 1976 actual prices and quantities and converged to equilibrium according to the assumptions outlined above.

Results

While total milk quantities, expenditures, and receipts will change relatively little with the presence or absence of regulation, the allocation of production between grade A and grade B producers will vary dramatically (table 2).

[5] This value was computed using 1976 quantity data (table 2) and estimated elasticity values (table 1).

Table 2. Comparison of 1976 Actual Regulated Dairy Economy with 1976 Simulated Unregulated Dairy Economy in Terms of Prices, Commodity Flows, and Values

	Actual Regulated			Simulated Unregulated		
Utilization	Grade A	Grade B	Total	Grade A	Grade B	Total
Fluid						
Price ($/cwt)	10.80	—	10.80	9.95	—	9.95
Quantity (bill lbs)	51.5	—	51.5	52.0	—	52.0

Total						
Price ($/cwt)	9.91	8.55	9.59	9.72	9.46	9.64
Quantity (bill lbs)	93.5	21.9	115.5	52.0	61.1	113.1
Value ($ bill)	9.27	1.87	11.08[a]	5.05[b]	5.78[b]	10.83[b]

[a] Value does not sum horizontally due to use of different data sources.
[b] Value does not sum vertically due to transportation costs which are subtracted out in the reactive programming solution.

The effect of regulation in terms of tax rates on fluid milk consumption and grade B milk production and in terms of subsidy rates on the production of manufactured goods is recorded in table 3. The effect of regulation is not as clear-cut on grade A prices. Generally, regulation imposes a tax on grade A production in the upper Midwest, northern Great Plains, and California regions while subsidizing grade A production in all other regions. Changes in economic surpluses also are recorded in table 3. These surplus changes are as predicted by the model and are a function of the implied tax rates. These surplus changes are also quite large and are composed of the indicated transfers and deadweight losses. The deadweight losses due to the misallocation of consumption (columns A and B) are generally small because of the inelasticity of demand.

Given the construction of the supply response for the model, dead-weight losses in production were redefined from the areas *C* and *D* shown in figure 1. The social costs due to resource misallocation between milk and all other production are recorded in column C and the social costs due to resource misallocation within milk production are recorded in column D, both in table 3.

The total deadweight losses were estimated as $96.8 million, the bulk of which comes from the production of grade A surpluses in a regulated environment. By comparison, Kwoka estimated $179 million to be the welfare losses of dairy market regulation and $750 million to be transferred from fluid milk consumers to grade A milk producers (corresponding to column E) for 1970. For 1973, Ippolito and Masson estimated total deadweight losses to be roughly $26 million per year, administrative costs to be roughly $34 million per year, and transfers corresponding to columns E, F, and G to be $334 million, $121 million and $105 million, respectively. As was pointed out by Ippolito and Masson, in addition to the deadweight losses due to regulation, the costs of administering the system must be added to determine the total social costs due to regulation.[6] Using the Ippolito and Masson administrative cost estimates of $34 million, the total social cost of dairy market regulation can be found to be $131 million for 1976. This $131 million includes the cost of both the price support program which purchased 1.9% of total manufacturing utilization in 1976 and the classified pricing and pooling program. If price support purchases had been greater, driving dairy markets farther away from the assumed unregulated equilibrium, the computed deadweight losses would have been larger.

Stability is one alleged benefit of dairy market regulation in that one result of regulation is the creation of grade A surpluses which insulate retail milk prices from the effect of annual supply and demand cycles. The model formulated to estimate transfers and deadweight losses does not provide a cushion for the short side of the grade A supply relative to the fluid demand cycle. However, the estimated supply and demand functions for the fourteen sample markets allowed the estimation of the mismatch between the grade A supply cycle and the fluid demand cycle. At constant prices, the maximum grade A shortfall of 9.0% occurred in the month of October, while the maximum grade A surplus of 13.0% occurred in the month of June. A 9.0% annual grade A surplus, which is sufficient to cover the short months was calculated to cost $7.0 million ($0.15/cwt × 9.0% × grade A supply).

Another frequently argued benefit of regulation is that regulation reduces the price risk for producers and the supply function shifts outward as a result of regulation. While the existence of this phenomenon is open to investigation, there are two implicit assumptions; first, that dairy farmers are risk-averse and second, regulation does indeed reduce the price variance. The testing of these assumptions will be left to a later time.

The supply structure in unregulated equilibrium was assumed to be the same as the observed supply structure in regulated equilibrium. The question asked of the model was how far must this supply structure have shifted out because of regulation in order for consumer surplus gains to offset the deadweight losses. It was found that if the regulated supply function had shifted out by 1.54% or more, then the deadweight losses would have been more than offset by the consumer surplus gains. The issue again becomes clouded by the possibility that regulation merely shifts risk from grade A to grade B producers. Given the level of belief in the stabilizing effect of dairy market regulation, the study of the existence of this effect and its relationship to producers' output decisions deserves more attention in the years to come.

[6] Some of these administrative costs go toward providing market information which is a benefit and will to some extent offset these administrative costs.

Milk Prices and the Public Interest: Discussion

Leo V. Blakley

A variety of conclusions and opinions on welfare costs associated with federal order regulation of milk markets has been presented in papers that can be classified as adversary, econometric, and evaluation papers. The classified pricing system, premiums over federal-order minimum prices, and allegations of nonvalues for expenditures associated with federal orders are the bases used for measuring social costs and income transfers.

The classified pricing system, by definition, results in income transfers from consumers of fluid milk and producers of manufacturing grade milk to consumers of manufactured milk products and producers of Grade A milk. The transfers are large, as shown by Dahlgran. One purpose of the classified pricing system is to increase producer prices, and modest increases have been obtained. Based on Dahlgran's 1976 equilibrium values of milk in all regions, the increase was \$0.07 per hundredweight, but with 2.3 billion pounds more milk produced in 1976 than in the simulated results.

Classified pricing under the orders does not maximize producer income but this failure to maximize income does not imply that there is "room for monopoly power." Control of quantity supplied would be necessary even to approach allocations which result in marginal revenues of zero (or above) in the three markets. There are no mechanisms under milk orders to achieve supply controls or even to prohibit milk producers in any geographic location from selling milk under an order in another region. Without controls on the production of milk there can be no monopoly.

Premiums over federal order minimum Class I prices constitute the basis for many of the social costs calculated by Masson and Eisenstat. Such premiums result from many factors as discussed by Christ and include costs of providing services to handlers, temporary shortages in supply, temporary surges in demand, and limited market power within spatially separated markets. Babb's model is superior to the Masson-Eisenstat models for estimating either the reasons for premiums over federal order minimum prices or the impact of market share on premiums. Babb, Bessler, and Pheasant (p. 57) found that if a 20¢ per hundredweight handling charge were the actual cost, and if it could be charged in all markets, the elimination of all other premiums would result in only a 3¢ reduction in U.S. blend prices. The portion of this 3¢ which was due to costs of solving temporary supply-demand problems in individual markets and the portion which was due to market power is subject to debate, but the latter is certainly less than the 3¢ per hundredweight.

Cross-market pooling (or the emotionally charged term of pool loading) was defined in such a way that a cooperative would automatically qualify for the charge of pool loading if it attempted to move milk to meet all Class I needs, minimize east-west movements (which have no price credits to offset transportation costs) and to minimize total transportation costs. There is no line around a market which can be drawn to say that a producer in a given location should always have his milk delivered to that market. If milk supplies are coordinated, it will not necessarily be picked up on the same farm assembly route on Sunday as on Friday. Neither can it be assumed rationally that the cost of servicing a market is constant with respect to market share or that a cooperative can always obtain the premium necessary to cover the cost of servicing the market. While widely separated markets offer the potential for small premiums based on the cost of shifting supplies from one market center to another, substantial premiums do not persist in the longer run since producers can change markets and both producers and processors can and do make new marketing arrangements.

Leo V. Blakley is a professor of agricultural economics, Oklahoma State University.

The "standby pool," contrary to the allegations, had its origin in discussion and planning long before implementation in 1967. The standby pool was initiated because there was nothing equivalent to Order 68, not vice versa. It was set up as a contractual reserve supply at an "insurance" cost equivalent for cooperatives to move fairly large quantities of milk if needed for contractual obligations. On individual days as much as two-thirds of the milk under contract was called for delivery. None was called in the flush period. The total milk under contract was small relative to either the uncommitted supply of Grade A milk or the annual rate of conversion from B to A.

How large are the social costs and how large compared with what? If $70 million were accepted at face value, the costs would represent 0.6% of the farm value of all milk reported by Dahlgran. Mueller (p. 6) regards this as a very modest figure in light of Scherer's estimates of 1.7% of gross national product for deadweight loss and transportation inefficiencies associated with the exercise of market power in the economy and a total market power cost of 6.2%. It also is modest compared with Greig's (p. 29) estimate of 3.6% to 5.0% of gross national product for social costs of imperfections in atomistic food markets. Greig's costs under competition include lack of economies of scale and firm size, excess capacity, and cross-hauls of plant mislocations.

Implicit in the calculation of social cost is measurement from the "purely competitive norm." I have no quarrel with the use of the competitive norm as an analytical tool, and it can be the basis for judging imperfections in our economic system. It cannot, however, be the basis for judging the consequences of altering economic and institutional arrangements on one side of the market.

The inference that elimination of federal orders and antitrust immunities for cooperatives will improve social welfare by the amounts reported is wrong for at least five reasons. First, the buyer side of the market is oligopsonistic; not purely competitive. Under a market order, the marginal resource cost and the supply price is approximately the same for all firms, and removal of federal orders would result in an income transfer from producers to the processing firms equivalent to the monopsony profit that could then be obtained.

Second, the measurements assume either given quantities of milk produced or the continued validity of supply schedules generated under federal orders and cooperatives. Dahlgran's analysis of uncertainty is not adequate, as he recognized. Moving back to marketing conditions in which producers do not know the price or whether a fluid milk market can be found each day would drive producers out. It is not as simple as a telephone call. In addition, the uncertainty would change the organization of resources at the firm level to be able to cope with variable prices and outputs. A major impact of this uncertainty would be on the structure of dairy farms. Up to 1974, dairy farming had less concentration of farm production than fifteen other farm enterprises (Jacobson, p. 20). About 83% had herds smaller than fifty cows. If small dairy farm numbers would decrease as much as cotton farms numbers declined when price uncertainty was substituted for price certainty, then small dairy farms would decrease by about 50% in five years. This would shift the supply schedule to the left and result in substantial increased social costs.

Third, as emphasized by Christ, consumers have benefited from price stability provided in part through reserve supplies accumulated under the support program. The curvature of the consumer demand schedule appears to be such that consumers lose when price instability of the type experienced for beef or grain in the 1970s is substituted for price stability.

Fourth, market order administrators perform services to both producers and processors which have value and would be required in the absence of federal orders. Minimum physical losses in plants, safeguards to ensure accurate producer milk weights, tests and quality, and assurances of proper accounting for use of producer milk represent some of the legitimate concerns which would entail costs to processors and producers.

Fifth, cooperatives perform most of the services involved in coordinating milk supplies to meet processing needs. Each firm can have deliveries of the quantities and qualities of milk at given plants and given times according to its own schedule of needs. The firm can choose the number of processing days per week and has the option of developing supplies of its own with purchases of supplemental milk needed to meet daily or seasonal variations in the demand for its products. The handling of reserve supplies associated with performance of the coordination function is costly, particularly in the high utilization markets of the southwest and southeast.

Stellmacher (p. 98) estimated the savings from centralized coordination in the southern region of AMPI have been 5.5 to 7.4 million dollars per year since 1968, just for the processing of 0.7 billion pounds of reserve supplies into manufactured products. These savings resulted from closing small inefficient plants and from minimizing the transportation costs of moving milk from farms to processing plants. The savings from elimination of duplicate farm assembly routes and from coordination of Grade A supplies now being analyzed would add to these savings. Substantial savings for comparable actions have occurred in the other regions for the 7 billion pounds of reserve Grade A and manufacturing grade milk processed into manufactured products.

An error, repeated often enough, sometimes gains acceptance by repetition and quotation. Such is the case with statements implying that classified pricing was initiated in response to farm conditions during and after the depression. Classified pricing in fact was initiated before 1920 because the alternative, flat pricing, led to problems of inadequate supplies during parts of the year and to problems with producers concerning the price level. The codification of this institutional arrangement after the depression was a codification of an arrangement which had been developed and was in operation in previous time periods. The basic institution of mandatory support prices for dairy products, on the other hand, was a product not of the depression but rather of an attempt to increase milk production during World War II.

Equating AMPI with Standard Oil or U.S. Steel is ridiculous. There are checks and balances on the management of a milk-marketing cooperative which do not exist for the management of a corporation such as U.S. Steel. The aim of the cooperative is to enhance producer income within the rules of the game in bargaining, merchandising, generic advertising, and product research. Producers have final control over management through member votes and boards of directors composed of members. The majority of members can change the board, the management, or the existence of the cooperative itself by their actions. I would not assert that every action or bragging statement by any person in the cooperative was always right, but I would assert that actions were undertaken with the objective of improving income of dairy farmers and that illegal actions by management would not knowingly be tolerated in the long run by most of the producers and board members I know. In addition, the marketing function is carried out under federal orders, and the administrators of these federal order programs should be commended—not condemned. In a fast-changing economic environment, changes in the rules have come quickly when questionable interpretations or possible abuses were involved. Innovations such as supply-demand adjusters which appeared good in theory have been implemented then abandoned when the desired results were not achieved. Finally changes in the rules for pricing properly have come slowly and after much deliberation.

In conclusion, I wish to thank the authors for presenting a variety of viewpoints concerning federal regulation of milk markets. The magnitude of social costs should always be under surveillance. It would be incorrect to infer that elimination of the federal orders with its public hearing process would result in increased consumer welfare. Most likely, the effect would be decreased consumer welfare as production decreased. Finally, I have refrained from entering into a discourse on the many allegations with which I disagree.

Milk Prices and the Public Interest: Discussion

Alden C. Manchester

This session and each of the papers owes its existence to the regulatory reform hypothesis and the flowering of debate stemming from it. This hypothesis holds that the regulation or legislation in question was initiated many years ago in one depression or another to meet conditions which were peculiar to those depression years. The depression is gone but the regulations are still with us. It goes almost without saying that regulations appropriate to depression conditions are quite inappropriate in the affluent eighties. Implicit in the argument is the conclusion that, because the legislation has not changed in major degree, the regulation likewise has not changed.

The "proofs" of the verity of this hypothesis are based on bad history, which almost completely ignores the transformation of milk-marketing orders from a system of local markets in the thirties to a national system of interrelated regional markets in the seventies.

A great many things indeed have changed since 1937, but some fundamentals have not. Milk is still produced every day and moved to market at least every other day. Despite the best management, cows do not produce on the schedule demanded by the buyers. This requires more management in balancing milk supplies than was needed during the depression. There are substantial economies of scale in balancing milk supplies, and cooperatives can achieve them. Despite economies of scale, there are still substantial costs in performing the balancing function. The firm which can avoid these costs by allowing someone else to perform the function receives substantial benefits. This applies to producers, cooperatives, and processors. Thus, many of the major reasons for the federal order program still exist.

Alden C. Manchester is Senior Economist in the Office of the Administrator, Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture.

The Antitrust Exemption

Section 1 of the Capper-Volstead Act provides that agricultural marketing cooperatives are partially exempt from the antitrust laws. Masson and Eisenstat—following the National Commission for the Review of Antitrust Laws and Procedures which followed the Antitrust Division's lead—recommend the dismantling of the Capper-Volstead Act. The only exemption preserved would provide that the act of farmers joining together to form a marketing cooperative would not be considered a conspiracy and therefore illegal. Marketing agencies in common and federations would be outlawed. Mergers between cooperatives would be subject to the same rules as those of other corporations, which would effectively prohibit mergers by cooperatives of significant size.

This is the extreme case of the application of the "small is beautiful" doctrine. In this view, the status of agriculture as the last redoubt of something resembling textbook-perfect competition is to be preserved at all costs. If the peasant farmer is too poor to support his family with dignity, some form of a welfare program is to be provided, but at all costs society is to avoid giving any market power. Cooperatives are acceptable as long as they resemble the handful of Rochdale weavers who started the cooperative way of life in 1844.

The Political Economy of Classified Pricing

The existence of classified pricing is an affront to economists, lawyers, and consumer advocates because, as everyone knows, classified pricing is equated with price discrimination. And price discrimination is illegal under the Robinson-Patman Act, although explicitly permitted under the Agricultural Marketing Agreement Act. So the lawyers know that is just another special favor for agriculture. Economists can look at the price discrimina-

tion diagram and conclude that consumer surplus is smaller and producer surplus larger with price discrimination than without it.

But all that glitters is not price discrimination. Economic price discrimination is defined as charging different net prices to different buyers for the same product. Nominal prices are easy to compare. Net prices are much more difficult, since they require substantial amounts of cost information as well as quoted prices. Comparison of prices for the same product requires that the product be identical in space, time, and form utility or that differences in these utilities be costed out into net prices.

It is argued by Masson that any difference in the price for milk from, say, a given tankload which is used for different purposes is conclusive evidence of price discrimination and of excessive market power on the part of the seller.

In any given tankload of milk, the objective characteristics of the parts of the lot used for fluid milk or for ice cream or butter-powder are certainly identical. But the value in economic terms of the milk used for ice cream is significantly less than that used for packaged milk. The economic principles embodied in location theory tell us that in a perfect market the value of milk for fluid use at a city plant is given by cost of transportation of bulk milk from the outer reaches of the milkshed, but the value of milk for use in ice cream is limited by the cost of transporting ice cream or ice cream mix from plants in the surplus production area. The economic forces represented by these principles are at work with or without the intervention of public regulation.

Thus, milk for use in ice cream can only move to a city plant at a price which does not exceed the cost of the other ingredients—e.g., ice cream mix—from somewhere else, providing there are no restrictions on movement or requirements that only local milk can be used to manufacture ice cream.

But, in this free-flow market, there will be no milk for use in fluid products if the higher price including transportation is not paid, because it obviously pays the producer better to sell to manufacturing plants in the outer reaches of the milkshed.

In terms of demand curves, the demand for raw milk for use in ice cream is zero if priced the same as that used in fluid products, because the entire demand already has been met by ice cream mix from more distant areas.

In such a situation, in a perfectly planned world, precisely as much milk would be produced in the local milkshed as was needed for fluid milk products and all ice cream would be made from shipped-in mix. But since cows produce varying amounts, storms interrupt assembly and hauling, and consumers do not behave according to plans, some mismatch between production on the farms and plant use for packaging is inevitable. It is obviously less wasteful to use the surplus milk (the reserve against running out) for manufactured products than to put them down the drain—which is now illegal in most jurisdictions because it creates additional load at the sewage plant.

Thus, that which is so crystal clear when one looks at a single, isolated tankload of milk takes on very different dimensions when one looks instead at the flow of milk day after day. Because it is the flow of milk which must be priced rather than a single lot, the dimensions of space, time, and form utility are changed. The "market" for that isolated tankload of milk at the dock of the city milk plant is only an incident in an interconnected set of markets for milk in all its forms and for all of its products.

Classified pricing of milk was invented to deal with these problems which are basically unchanged in 100 years. The additional possibility of price discrimination was discovered much later. It had to await the development of market power.

According to the calculations of Masson and colleagues, the social costs of federal and state regulation were $30 million in 1973, and those of "cooperative monopoly power," $41 million. This equals 0.8% of consumer expenditures for fluid milk and cream or about 1.1¢ per gallon. We are told that up through early 1978 over half of the "cooperative monopoly" social costs have been eroded by the beneficial effects of the consent decrees. Rising transportation costs since 1973 which were not offset by increased transportation allowances under federal orders probably would more than wipe out the calculated social costs of federal and state regulation.

The magnitude of these social costs fails to strike terror in my heart—1973 social costs of 1.1¢ a gallon simply fail to impress. Discussion of such magnitudes is reminiscent of the heated arguments of medieval theologists over how many angels could dance on the head of a pin.

But persist we must, for even these insig-

nificant amounts ignore reality. Ignored is the comprehensive analysis of Babb and associates (Babb, Bessler, Pheasant) who find no significant effect of cooperative market power, whether measured by the market share of one or four cooperatives, on the size of over-order payments.

Even more serious to a consideration of the validity of these or anyone else's estimates is their ignoring the costs, other than transportation, of marketing bulk milk for use in fluid milk products. These costs exist and must be covered by the marketing system in one way or another. They are not the result of monopoly power. On the contrary, they would be much higher if large cooperatives were broken up and the system no longer had the benefit of economies of scale. An exemplary study by Christensen and associates (Christensen, Petterson, Swainston) found these costs to be about 50¢ per hundredweight in 1977, which would be nearer 60¢ today.

Thus, I conclude that the social costs of federal and state milk regulation and of cooperative market power as measured by Masson and company are either insignificant or nonexistent. The omissions I see would all have the effect of lowering their estimates. Unless someone else perceives major omissions or errors which would raise the estimate, I see no reason to try to do it better.

On the other hand, the benefits so cavalierly dismissed by Masson and Eisenstat are far from trival. For better or worse, economics lacks the conceptual basis and measurement tools to deal with dynamic problems, so we cannot measure the benefits of stability. Clearly, the combination of the federal price support and milk order programs and of cooperative activities have provided a major element of stability in dairy production markedly different from that in other parts of animal agriculture. It seems to me highly significant that milk production is far-and-away the least concentrated in animal agriculture except for hogs, where the limits are set by disease problems. Dairy farming is still family farming, which can hardly be said for integrated production of eggs, broilers, or turkeys, or for large-scale cattle feedlots. No other sector of animal agriculture has federal programs, nor are cooperatives of major importance. The prudent policy maker concerned with the public interest might be well-advised to consider this phenomenon carefully before he decided to abolish the programs in question.

Post-Keynesian Economics and Agriculture
(Edna T. Loehman, Stanford Research Institute, Chairperson)

Agriculture and the Rest of the Economy: Macroconnections and Policy Restraints

Graciela Chichilnisky and Lance Taylor

The economic relationships between the agricultural and nonagricultural sectors have long been scrutinized, with a number of key linkages singled out—investment requirements and the macroadjustments between the two sectors that permit savings to come forth; nonagricultural demand for employment and food confronting agricultural supply response; shifts in income distribution that ensue as people move from agricultural/rural to nonagricultural/urban occupations and economic roles. In this paper, we develop diagrammatic models to illustrate short- and long-run aspects of these two-sector interactions and their implications for policy. Both models are "post-Keynesian" in their focus on Keynes-like savings-investment approaches to the macrosystem, and Ricardo-like determination of the functional income distribution via the real wage. But they also follow tradition in addressing questions under debate for decades and likely to be controversial for time to come. In that sense, we add only novel presentation and a few modern twists to strands of macrotheory that Arthur Lewis, Simon Kuznets, Richard Eckaus, Latin American structuralists, and the participants in the Soviet industrialization debate started to spin long ago.

The first two sections of the paper are devoted to a combination of the Kuznets and structuralist stories, where we ask how the agricultural/nonagricultural terms of trade and income distribution must adjust to permit both savings-investment and commodity market balance to be assured. It will be shown that inflationary processes can easily be kicked off by terms of trade movements in the short run. In the next two sections we follow Chichilnisky in working out a longer run, Lewis-style model in which economic dualism plus an elastic labor supply can lead to severe problems with realization of the marketed surplus and agricultural exports abroad. A brief final section summarizes the major implications of the models for policy choice.

Investment Demand, Savings Supply, and the Terms of Trade

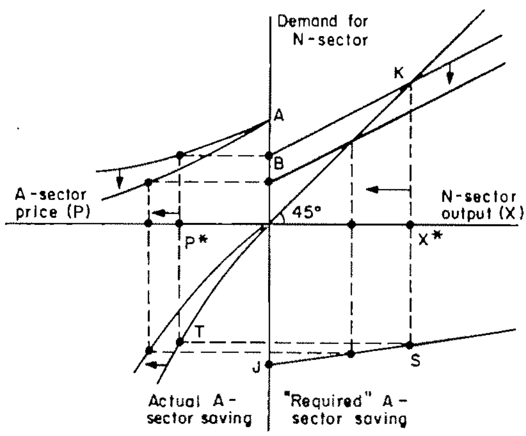
The agricultural terms of trade are supposed to balance many forces—food demand, producer supply, and agricultural savings in response to investment needs. Which factors dominate movements in the terms of trade and which are relatively unimportant may vary with the conjuncture, and more generally with the institutions of the economy at hand. In this section, we present a four-quadrant diagram which helps isolate controlling forces and we identify the conditions under which each may reign.

The general equilibrium of the terms of trade appears in figure 1. The equilibrating variables are the price of agricultural (or A-sector) output, and output itself in nonagriculture (N-sector). The diagram shows how these variables are determined jointly in the market for nonagricultural goods in the upper quadrants and by aggregate demand and supply (or savings and investment) below. When both savings-investment and N-sector commodity balance are in equilibrium, then so will be the market for agriculture by Walras's Law.

To explain the diagram we discuss the relationships depicted in each quadrant, beginning with the northwest. The agricultural price is measured on the horizontal axis running left from the origin, and demand for nonagricultural products on the vertical axis pointing up. Demand faced by the N-sector is the sum of three components, *viz:* (*a*) autonomous de-

The authors are, respectively, associate professor of economics at Columbia University and professor of economics, Massachusetts Institute of Technology.

Research for the paper was partly supported by the United Nations Institute for Training and Research (UNITAR).



Note: A two-sector model in which the agricultural price varies to clear its market (*A*-sector) while nonagricultural output (*N*-sector) adjusts to meet effective demand. A downward shift in the agricultural supply function leads to less real saving from the *A*-sector and less demand for *N*-sector products, for a given agricultural price. The outcome is an increase in the *A*-sector price, and a fall in *N*-sector output.

Figure 1. A two-sector model

mand for government consumption, investment, and exports, at point *A*. (*b*) Demand from agricultural incomes. This increases with the agricultural price *P*, because of rising farm incomes and price-substitution responses in farmers' demand functions.[1] (*c*) Demand from nonagricultural incomes will fall as *P* rises, for a given nonagricultural output *X*. The stylized fact is that food and most raw material demands are price inelastic; thus an increase in *P* will lead to increases in money outlays for agricultural commodities, and decreases in nonagricultural real income and purchases of nonagricultural goods.

The response to price of the sum of these demands has an ambiguous sign. In the northwest quadrant of figure 1, we have shown the income effect in demand from nonagricultural incomes as dominant, so that as *P* rises, demand for nonagricultural products drops off. At price P^*, the market demand facing the *N*-sector (at zero level of output *X*) is *B*.

Consumption of nonagricultural goods also responds to incomes generated in that sector. For simplicity in the diagram, we assume that the price of *N*-goods is fixed by a constant mark-up over urban prime cost (the short-run numeraire) and also that there is excess capacity in the sector. Its consumption function takes the usual Keynesian form, a straight-line rising function of *X*, beginning for the agricultural price P^* at point *B*. The northeast quadrant is a Keynesian cross, determining equilibrium at point *K* where the consumption function meets the 45°-line. For price P^*, nonagricultural output is pegged at X^*.

Together with the market for nonagricultural goods, the savings-investment balance serves to close the model. The southeast quadrant shows the amount of savings "required" from agriculture (required savings = investment − savings from nonagriculture), a declining function of *X*. For high enough *N*-sector output all autonomous expenditure could be matched by savings from nonagriculture alone, at a point far to the right on the axis for *X*. On the other hand, if *X* fell to zero, agriculturalists could presumably manage to generate all savings required—point *J*. In practice, the economy will lie somewhere between these two extremes. However, with low marginal savings propensities from nonagricultural incomes (not improbable in LDCs), savings supplied from the *N*-sector will not be highly responsive to output *X*. Required savings from agriculture will mostly be determined by investment or, in the representation of figure 1, the trade-off relationship between the two sources of saving will be rather flat.

Savings supply from agriculture will of course rise with the sector's income, as determined by the price (via the supply function). The southwest quadrant of figure 1 sketches agricultural savings as a function of price. Savings-investment balance occurs at the price and output pair P^* and X^* where savings generated from agriculture at level *T* is just equal to the amount required at *S*. From the accounting implicit in the diagram, the agricultural savings will have to take the form of a trade surplus with respect to the nonagricultural sector. The flat curve in the southeast quadrant means that the required surplus in terms of nonagricultural goods is pegged by investment demand. The price *P* (and the terms of trade) adjust to permit the surplus to appear.

The points P^* and X^* in fact represent a full equilibrium in which the commodity market and savings-investment are both in balance. The two equilibrating processes can be summarized in one diagram, by consolidating the upper and lower quadrants of figure 1 sepa-

[1] Very strong income effects in farmers' demand for their output could make their nonagricultural purchases fall as *P* goes up. In the present model we assume away this marketed surplus problem, though it is central to the model of the sections below.

rately. On the savings-investment side, the southeast quadrant shows that required agricultural savings is a declining function of X. On the other hand, savings supply from the A-sector rises with P. Thus, in equilibrium an increase in P has to be accompanied by a fall in X, to keep savings-investment in balance. This relation is drawn as the "Saving-investment" curve in figure 2.

The story in the commodity market is slightly more complicated. As figure 1 is drawn, an increase in nonagricultural output (determined by the Keynesian cross in the northeast) will have to be accompanied by a fall in P. The dominant mechanism is the income effect in nonagricultural commodity demand—a decrease in P raises nonagricultural real incomes enough to stimulate overall demand for X. Again we derive a negative relationship between P and X. For stability, the slope has to be less steep than in the savings-investment balance, as shown by the "Commodity market" line in the left-hand diagram of figure 2.

The other possibility is that increases in P will stimulate aggregate demand for X, via rising farm incomes. This case is more likely when the agricultural sector is large relative to nonagriculture and is illustrated by the rising "commodity market" line in the diagram to the right in figure 2.

Comparative Statics of Output Levels and the Terms of Trade

Changes in policy or exogenous variables can be viewed as shifting one or more of the curves appearing in figures 1 and 2—the diagrams show how agricultural price and nonagricultural output adjust to re-establish a disturbed equilibrium. We work through several examples in this section. They reveal that interactions between sectors hold enough potential surprises to keep the macropolicy team alert.

First, figure 1 itself demonstrates what happens when there is a downward shift (due to bad weather, say) in the agricultural supply function. For a given agricultural price, agricultural income will be lower because of the loss in output. There will be both less savings and less demand for N-goods originating in the A-sector, causing the curves in the northwest and southwest quadrants of figure 1 to shift toward the horizontal axis. Tracing around responses in the diagram (beginning at point S, say) shows that P must rise and X fall in the new equilibrium—the whole graphical structure is displaced to the left. The adjustment mechanism is the slide downward of the demand curve in the northeast quadrant—aggregate demand is reduced by the income loss attendant upon falling agricultural supply.

The sort of supply shock shown in figure 1 easily can set off a burst of inflation, if money wages respond to the rising agricultural price and (as discussed in more detail below) drive up N-sector costs in turn. A sequence of such shocks could keep inflation going if, for example, population growth runs ahead of the growth rate of agricultural supply. To deal with such a process formally would take us too far afield, but the reader will recognize its affinity to the Structuralist inflation model that Sunkel first proposed.[2]

A second set of implications can be drawn regarding agricultural trade. For simplicity, assume that imports come in under a quota or exports go out through a marketing board; in effect, the government regulates the quantum of trade. In figure 1, the upper quadrants will not be affected by changes in trade policy, because they relate internal incomes and prices to N-sector demand. In the lower quadrants, however, required saving from agricultural income will react to trade policy shifts. An increase in agricultural imports or reduction in exports, for example, will lead to an *ex ante* increase in the trade deficit or foreign saving and a reduction in A-sector saving required. As shown by the shifted "savings-investment" curves in figure 2, a lower level of X (and N-sector saving) is then consistent in equilibrium with a given P (and agricultural saving). The final outcome depends on whether N-sector demand responds positively or negatively to P. In the latter case (where N-sector income effects are important), an increase in agricultural imports will cause P to fall and generate enough demand to lead to an increase in X (left side of figure 2). Both changes would favor urban dwellers, under conditions in which their share in economic activity (and N-sector demand) is large. In the circumstances, a political coalition in favor of gaining easy access to imports could form. Examples might be the groups favoring repeal

[2] See the paper by Eliana Cardoso for an elegant description of a Sunkel-type inflation in an independent development of essentially the same model as in figure 1. Taylor provides additional background.

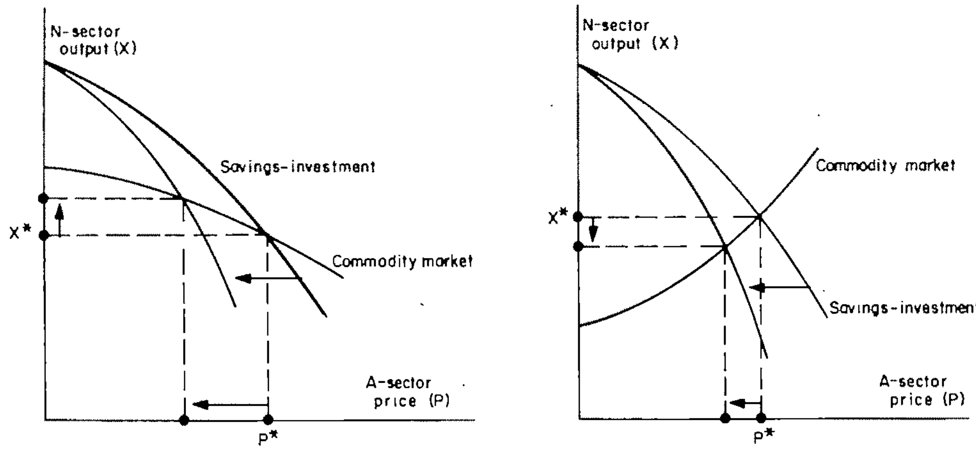


Figure 2. Model of the agricultural and nonagricultural sectors expressed in terms of equilibrium (P, X) combinations in the nonagricultural commodity market and the savings-investment balance

of the Corn Laws in England in the last century, or the domestic supporters of low-cost Japanese acquisition of rice from Taiwan and other locales before World War II. By contrast, in the large-agriculture case, shown to the right in figure 2, the increase in imports causes P and X to fall. Liberal import policies might be opposed by most domestic interests in this case, whereas only agriculturalists are penalized in the situation at figure 2's left.

Increases in exogenous demands for nonagricultural goods generate a third comparative static tale. The analysis is a bit tricky, so we take it in steps.

The initial impact of the demand increase is to shift both autonomous demand for nonagriculture (point A in figure 1) and the base level of required agricultural savings (point J) away from the origin. Assume for a moment that demand for nonagricultural products is independent of P. Then the demand increase will lead to a higher X from the Keynesian cross in the northeast. The subsequent impact on required agricultural savings in the southeast appears to have an ambiguous sign, because X rises (lower required savings) but J moves away from the origin (higher required savings for a given X). However, the problem vanishes when we recognize that the demand response in the northeast is subject to an expenditure leakage that does not matter in the southeast. The Keynesian cross shows multiplier demand stimulated by X for itself, after demand for agricultural products from nonagricultural income is netted out. The southeast quadrant shows the gap between investment and overall savings from incomes generated by X. The difference shows up in a positive response of required savings—and thus of P—to the increase in autonomous demand.

Now reintroduce the dependence of N-sector demand on P. By LeChatalier's principle, a positive relationship means that the increase in X just discussed will lead to further demand increments through the price mechanism, so the initial increase in autonomous spending will be reinforced. On the other hand, a negative relationship between P and demand (as actually shown in figure 1) will dampen the initial increase in X, and might even leave a final negative effect of autonomous spending on nonagricultural output. This extreme response is unlikely, but the analysis does show that when agricultural products are a large part of the consumption bill of a non-negligible urban population, then weak or ambiguous output responses to fiscal initiatives may be the rule. Semi-industrialized countries are particularly prone to such ills.

A fourth story is based on an increase in the marginal propensity to consume from nonagricultural incomes, for example, from an income distribution shift. For given levels of autonomous spending and the agricultural price, the demand line in the northeast quadrant of figure 1 becomes steeper, leading to an incipient increase in X. In the lower quadrants, the result would be a fall in required agricultural savings and P, if the response curves stayed put. However, the increased propensity to consume will lead to a lower propensity to save, and the required agricul-

tural savings curve in the southeast would flatten out. The flattening, in fact, would be strong enough to lead to a higher agricultural price, for the reason sketched above—part of the consumption increment in the northeast quadrant leaks to demand for agricultural commodities, while the whole effect is captured in the savings response below. In the northwest quadrant, the price increase would lead to additional demand for nonagriculture if it responds positively to P, or dampen the initial impact in the opposite case. Once again, income effects can foil the expansionary impact of an increase in the nonagricultural propensity to consume. But prices will rise regardless of the output response.

Finally, consider an increase in the urban money wage. From the assumption of mark-up pricing, the wage increase will drive up the price level, perhaps after a lag. For an unequal urban income distribution (as postulated by Kuznets and—indeed—Lewis) it also may increase the overall propensity to consume, as the wage bill rises relative to total profits and import costs.

We can decompose the effect of the wage increase, using results previously derived. The nonagricultural price increase cuts back on the purchasing power of agriculture, shifting the curves as in the left-hand quadrants of figure 1. Hence, we would expect the agricultural price to rise and nonagricultural output to fall from the wage increase.

At the same time, the nonagricultural propensity to consume goes up. As just discussed, P will be given another upward nudge, but the output response can have either sign. In sum, the wage increase will lead to higher prices in both sectors, but output can shift either way. In at least one empirical model embodying agriculture/nonagriculture interactions of the type stressed here, an urban wage increase leads output to expand (see McCarthy and Taylor). The rising wage offsets the loss in aggregate demand implicit in any downward shift in the agricultural supply function, but only at substantial inflationary cost. The dilemma posed by the structuralist inflation model sketched above begins to bite.

Economic Dualism, Marketed Surplus, and Trade

The model just described lets the agricultural price vary to clear the market, with income distribution shifts between the sectors bringing aggregate demand in line with supply. Now we take a somewhat longer term perspective, in which technological conditions, factor supply functions, and patterns of demand dictate economic response. Specifically, we consider an economy in which there is technological dualism in the sense of wide differences in technique between the sectors (with the capital-labor ratio being substantially higher in nonagriculture), surplus labor due to a highly elastic labor supply function, and heavy concentration in demand from labor incomes on agricultural (or food) commodities. Largely to avoid unilluminating mathematics, labor and capital are assumed to be freely shiftable between the sectors, and fixed coefficients for these inputs characterize technology in production. The model thus is based on assumptions stressed by Lewis and Eckaus.

Sectoral interactions are easily described using standard results from the theory of international trade. Let the nonagricultural price be the numeraire. Then by the assumption that agriculture is labor-intensive, an increase in the agricultural price P will increase the wage w and lower the profit rate r. The real wage in terms of food ($q = w/P$) is also an increasing function of P, on Stolper-Samuelson lines. However, as P rises it has an increasingly weaker positive effect on q (the second derivative is negative), due to a rising relative cost of capital inputs. (See Chichilnisky for a proof, as part of a full formal development of the model.)

By the surplus labor assumption, the increase in q in response to P will pull more workers into production according to the labor supply function.[3] But since agriculture is labor-intensive and the capital stock is fixed, total agricultural output will increase by the Rybczynski theorem. The mechanics are illustrated in figure 3. A rising agricultural price provides more labor along the curve in the southwest quadrant, which in turn stimulates an increase in agricultural output (Z) in the southeast. Reflection around the 45°-line in the northeast quadrant allows measurement of Z on the vertical axis pointing up. Reading the diagram in reverse shows that an increase in demand for Z (for export, say) would have to

[3] Figure 3 is drawn assuming an inverse supply function of the form $q = q_0 + \beta L$, where q_0 is the "subsistence" real wage at which no employment would be forthcoming, and L is total employment. In a surplus labor situation, the coefficient β will be very small.

be accompanied by more employment and a higher agricultural price.

So far, so good: agricultural supply response depends on price in a dual economy. But nothing has been said regarding how the extra labor income from more A-sector output gets spent. Suppose that a large share of the increment goes toward purchases of agricultural goods. Demand mirrors the increases in employment and output, so that excess agricultural supply after sales for personal consumption may not be very price responsive at all. The northwest quadrant of figure 3 illustrates a case in which around 90% of wage income is spent on "food." The example is exaggerated, but does illustrate for the two prices traced around the quadrants how A-sector output minus demand increases only slightly as the price P is doubled. Indeed, at higher levels of P the excess supply response may even be perverse. When restated in a plausible though simplified general equilibrium model, the traditional marketed surplus problem is far from being as trivial as it sometimes has been made out to be.

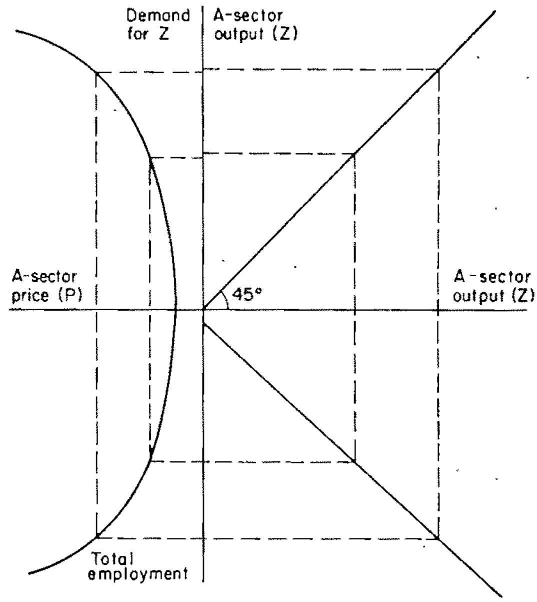

Figure 3. Impact of changes in the agricultural price on the sector's excess supply in a model with highly elastic labor supply, production dualism, and a large share of wage income devoted to food

Marketed Surplus Woes

Figure 3 illustrates an income distribution problem faced by countries in which the wage good is used for export. An increase in the price to call forth extra supply is frustrated, because the extra income resulting from increased production largely goes to wage good demand.

Policy choice under these circumstances is difficult, as experience in a number of countries suggests. When the agricultural product is exported (wheat or beef in Argentina, rice in Thailand) the government often tries to drive a wedge between the acquisition and sale price of the wage good, to cut real consumer income and demand while maintaining supply. Such policy may fail on other grounds, however. An example is increasing resistance on the part of profit-income recipients to shifting the income distribution toward agriculture via the high supply price. More generally, the economic system is Walrasian unstable (or nearly so), which makes management via the price system a delicate task.

Even in a closed economy, where the wage good is not traded and A-sector demand must equal supply, similar problems arise. For example, an increase in the capital stock will shift the intercept of the line in the southeast quadrant of figure 3 away from the origin.[4] For a given employment level, the diagram shows that the result would be a decrease in agricultural supply as resources move toward the capital-intensive, nonagricultural sector. With demand limited by supply the agricultural price P would have to fall to reduce labor income (northwest quadrant), leading via a lower real wage to decreased labor supply in the southwest. After subsequent rounds the process could converge at a lower (or at best slightly higher) level of employment overall.

What these results show is that internal demand conditions do not permit easy absorption of the capital-intensive good. In Eckaus's terminology, there is a "factor proportions" problem, exacerbated by patterns of demand. A bowdlerized Marxist interpretation would be that surplus from nonagricultural production cannot be realized. Confiscatory income realignments against wages by a government favoring nonagriculture would shift the demand curve in the northwest quadrant toward the horizontal axis, and permit realization to

[4] The intercept represents the level of employment when agricultural output is zero and all available capital is used to produce the nonagricultural good.

occur. An example would be state purchases of the nonagricultural good financed by a levy on labor income. The Stalinist resolution of this set of difficulties (first enunciated by participants in the Soviet industrialization debate of the 1920s) might be interpreted along these lines.

Problems with Policy Change

The problems raised by the dual economy model could be pursued further. For example, its potential Walrasian instability can be countered by the government acting as a Marshallian stable purchasing agent, as explored by Chichilnisky. Similarly, if the supply of capital is also price-sensitive, the transformation curve between agriculture and nonagriculture can cease to be concave to the origin—see Chichilnisky and Heal. These difficulties ultimately arise from production dualism, factor supply functions, and demand behavior, all tending to destabilize the system in the same way.

Somewhat similar observations apply to the model discussed in the first two sections of this paper. The relative price insensitivity of food demand and the role of agricultural incomes as a savings source go together there to generate potentially perverse responses to standard policy ploys. In particular, agricultural supply shortfalls may be highly inflationary, fiscal spending may not stimulate aggregate demand, extra food imports will have strong effects on the intersectoral income distribution, and demand may react positively to an increase in the money wage.

The implications of these results for policy are sobering, insofar as the models adequately replicate sectoral interdependencies in real economies. In a two-sector framework, modest ingenuity suffices to generate difficulties of the type emphasized here. The question is whether or not the models capture slices of likely economic response. Our view is that they do, and that the problems faced by policy makers in poor countries are economically real and severe. But we would be delighted if we were wrong and would welcome demonstrations that such is the case.

Food System Organization and Performance: Toward a Conceptual Framework

James D. Shaffer

My purpose is to explore some ideas and problems concerning a conceptual framework for organizing knowledge of the relationship between political-economic organization and performance, with application to the U.S. food system. The connection with post-Keynesian economics is that of a common belief that existing paradigms are inadequate to inform some critical economic policies, especially those involving stagflation. This is stimulating a reexamination of assumptions about important variables and relationships. Most notable is the examination of the role of the market and the micro-macro relationships (Galbraith 1978).

I put the paper in the context of the program of research on "Organization and Control of the U.S. Food Production and Distribution System" established as regional research project NC 117. The general objective of the project is ambitious: to describe the existing organizational system for producing and distributing food products, to identify the economic and institutional forces that are changing this system, to forecast where present trends may lead, to set forth alternative public policies that could affect the system of the future, and to appraise the alternatives in light of the values and goals held by the various sectors of the population.

Work to date on the project has been organized along three general lines of inquiry: (*a*) industry studies, i.e., food retailing, (*b*) studies of subsectors and vertical coordination systems such as the dairy subsector, electronic exchanges, and procurement practices of retailers, and (*c*) studies of the legal environment such as antitrust laws applied to the food system.

The analytical framework has been eclectic. Industry studies have tended to be conceptually organized by the Industrial Organization framework (IO), which is a structure-conduct-performance (S-C-P) paradigm grounded in price theory. The subsector studies have paid more attention to the internal decision making of the firm and thus draw from work in organizational behavior. The dominating framework of the group has been an expanded S-C-P. The basic concept of the paradigm is that market structure strongly influences market conduct of firms which in turn influences market performance. Market structure variables include number and size distribution of firms, entry conditions, and product differentiation. Market conduct refers to pricing policies, sales promotion actions, decisions on product characteristics, and actions by competitors to coordinate market behavior. Market performance is concerned with allocative and technical efficiency, progressiveness, product characteristics, and equity (Marion and Mueller). The extended S-C-P framework looks at the influence of government programs and regulations on market structure, conduct, and performance and expands the notion of performance to a more aggregate system concern with such outcomes as income distribution, employment, inflation, level of living, and the distribution of economic and political power.

All models necessarily abstract from the conditions of the real world. The S-C-P framework tends to omit aspects of reality I would like to stress in attempting to extend the scope of the paradigm. The IO model attempts to explain the conduct of firms by concentrating on the competitive environment and other economic conditions external to the firm such

Michigan State University Agricultural Experiment Station Paper No. 9265. This paper is part of the Michigan contribution to regional project NC 117.

The paper benefited from comments and assistance from H. Riley, C. Chase-Lansdale, A. Schmid, C. Cordes, B. Ferres, J. Schmelzer, and E. van Ravenswaay.

as the characteristics of demand and technology. The basic unit of analysis is the "relevant" market. The firm is treated as a "black box." At the same time, an extensive literature has developed dealing with intrafirm decision making and the behavior of organizations which has had little influence on price theory and other economic analysis. Babb and Lang have explored the implications of this work for research on the food system. By avoiding consideration of firm decision making, IO tends also to avoid the problem of uncertainty. Thus, the pervading problem of coordinating economic activity, investing, and producing in one period to meet demand in future periods, is generally external to the model. Finally, the performance of the food system depends upon the behavior of many organizations including governments, households, and associations of firms. I would like to explore a framework which would consider at least some aspects of this reality.

The extended S-C-P framework has contributed to valuable research. Marion and Mueller provide an insightful discussion of research on the food system from this perspective. My hope is to encourage additional conceptual work which will help with the type of analysis implied by the objective for the NC 117 project.

General Approach

Start with the most elementary and global concept. At a point in time participants in a political economy exist in an environmental situation which is their opportunity set. Each participant responds to his environmental situation and the aggregate consequence is a change in environment. The changes in the environment contain the benefits and costs for individuals and groups which follow from the behavioral responses. Changes in participants' perceptions of the environment and appropriate behavior follow from the change in the environment. The sequence continues, the system evolves. Call the total flow of consequences which follow from the organization of the political economy, performance. Then we can say that the evolving system is driven by this basic three-term sequence of environment, behavioral responses, and performance—E-B-P . . . E-B-P . . . .

Obviously, no conceptual framework can deal with the complexity implied by this three-term sequence. The task is to classify strategic characteristics of the environment, classify participants and their behavioral modes, classify outcomes, and develop meaningful hypotheses about their relationships.

Environment

The environment can be thought of conceptually as overlapping opportunity sets. The physical environment, or aggregate physical opportunity set at any one time, sets the outer bound of the possible payoff matrix for society as a whole. The political-economic system structures relationships among participants, thus structuring the opportunity set for individuals and groups by defining rules for access to resources and payoffs from the aggregate opportunity set. An individual opportunity set is a function of location in the political economy. The individual participates in the political economy as a member of organizations—governments, firms, households, and other associations. Thus, his opportunity set is governed by the external environment and the internal structure of the organizations and his positions.

Individuals articulate preferences, that is, seek their goals, through market, political, and social transactions. Transactions carry information, influence, benefits, and costs. Transactions take place within organizations and between organizations. A fundamental issue in political economics is the determination of the mix between market and political processes for preference articulation.

The external environment of organizations includes: (*a*) factor and product markets, which would include the extent and product content of the market plus all of the variables considered part of structure in the S-C-P framework; (*b*) the system of rights and regulations, broadly defined, which includes property rights, enforcement of contracts, all economic regulations, taxes, and subsidies; (*c*) perceived social and political pressures and expected markets, which introduces the idea that organizations respond to perceptions of the future. This includes the influence of ideology—a general agreement about acceptable behavior. Behavior outside of the prevailing ideology implies the possibility of sanctions and is a pervasive constraint, and (*d*) the technical transformation functions.

Performance

In the dynamic framework, performance is a complex concept. Performance is the outcome of the behavior of the sum of participants acting within the constraints of their perceived individual opportunity sets. The aggregate consequences are the changes in the environment. The changes include both the physical environment, i.e., production and consumption, and change in the political-economic structure. The outcome of one period is an input to subsequent periods. The outcome contains the distribution of costs and benefits to the participants. The expected distribution of benefits and costs contains the incentives for the behavior. Among the consequences is the change in perceptions and preferences of participants influenced by this experience.

Now comes a fundamental problem of the political economy and of organizations. The individual participant is exposed to only a small portion of the aggregate opportunity set, and only some of the consequences of behavior accrue to the individual. That is, the individual acts on the environment in terms of his perceptions of the consequences. Perceived consequences that will be most immediate and act as incentives usually will be those that fall directly on the participant and are linked directly to specific behavior. The management system of an organization is intended to structure individual opportunity sets, incentives, and sanctions in such a way that individual behavior is congruent with the objectives of the organization.

This pervasive problem is recognized in part in economics in such concepts as market failure, externalities, free riders, and public goods. Schmid provides an in-depth study of the problem of external consequences in public choice. Shaffer (1979) looks at regulations from this perspective.

For the political economy the combination of the market and regulatory system structures what consequences of behavior are taken into account by firms and other participants. Actions through both the political system and the market alter the aggregate and individual opportunity sets. That is, the available factors, products, and incentives are influenced. The opportunity set of each individual is coercive. It rewards and punishes and thus channels behavior.

Time and uncertainty create many problems in structuring individual opportunity sets through regulations and markets in such a way that consequences of individual behavior are congruent with goals. Actions and consequences are separated by time, and direct connections are difficult to establish. The future payoffs from actions are uncertain, future preferences are uncertain; uncertainty is pervasive. Political-economic activity involves complex sequences with complex patterns of uncertain consequences. Understanding such sequences is the interesting challenge of political economics.

One of the problems in public policy is to identify relevant classifications of performance. The definitions of both relevant dimensions of performance and performance indicators are conceptual problems and such concepts would be an important part of a fully developed conceptual framework. Among those considered important are total production, product mix, employment, inflation, and distribution of benefits. Many other consequences are important but lack performance indicators.

Behavior

The link between political-economic organization and performance is the behavior of individuals and organizations. We need to incorporate concepts about behavior into the conceptual framework to form the basis of realistic assumptions for theory development and for practical policy analysis. My basic assumption is that individuals search narrowly selected portions of the environment and identify patterns of behavior consistent with their perceptions of that opportunity set which will satisfy them. Thus, I suggest starting with the concepts of satisficing behavior and bounded rationality. Simon, in his Nobel lecture, eloquently supports the incorporation of these concepts in the theory of decision making in firms and administrative units. He assumes the decision maker has limited capacity and operates in an uncertain environment. Among the procedures adopted to solve problems is to look for satisfactory choices rather than optimal ones, replace abstract goals with tangible ones, and divide up the decision-making task among many specialists.

I assume the participant develops multiple goals and many techniques to satisfy the goals. Techniques are patterns of behavior, adaptive and strategic, which are perceived as appro-

priate in dealing with particular situations embedded in the individual's perceived opportunity set. Perception is selective and influenced by experience. The technique may or may not be effective (optimal) behavior given the objective environment.

Techniques will include (*a*) the opportunistic behavior—"self-interest seeking with guile" suggested by Williamson (p. 26) as "having profound implications for choosing between alternative contractual relationships"; (*b*) decision processes similar to maximizing processes often assumed in economics; and (*c*) the behavior of Hirschman's slacker.

Much conceptual and empirical work remains to be done in incorporating learning, decision making, and search processes into a political economic framework. I am impressed with some of the insight from the concept of contingent reinforcement which forms the basis for a theory of learning (Platt). This involves a three-term sequence (situation-behavior-reinforcement) and could be interpreted to a statement such as: At any particular time an individual is in a situation, responds to it by changing the environment, and the change in the environment influences (reinforces positively or negatively) the individual's future behavior, he learns. He learns techniques or complex patterns of behavior as a result of payoffs from the environment. The payoffs (reinforcers) are contingent on particular patterns of behavior.

However, this theory is, I believe, too limiting for our understanding of political-economic behavior. It is useful to think of economic behavior in terms of goals, preferences, plans, expectations, etc. while recognizing they are all learned, including learning from communication, cognition, and especially imitation.

Collective Action

Participants seek their goals primarily in environments of collective action and decision making. The primary types of organizations in the political economy are firms, households, unions, and governments, although many other types of associations are also important. These organizations shape the opportunity set of their members and the interaction of organizations shapes the opportunity set of the organizations.

What differentiates this aspect of the E-B-P framework is the proposition that participants have individual and different perceptions about appropriate behavior to achieve general goals of the organization and have personally held preferences they will seek to articulate within the opportunity structure of the organization. The behavior of the organization follows from the political interactions of the participants and there is no meaningful objective function for the organization independent of this political process. It is further assumed (as does Leibenstein) that each participant has some discretion in the amount and in the application of effort, and no one in an organization knows with certainty the consequences of the collective decisions.

In this section I first suggest a tentative analytical framework for examination of participant behavior in organizations in general and then briefly comment on a few characteristics of firms, households, and government. Finally, I comment briefly on the market as a coordinating mechanism.

Organizations

The conceptual framework identifies four classes of variables which influence the behavior of the organization: the external environment, the organizational structure, the organizational control procedures, and individual perceptions and preferences (see Roberts).

The external environment of an organization was discussed previously. It represents the opportunity set for the organization and thus disciplines the behavior of the organization. The aggregate benefits available to members depend upon the collective ability to exploit the organization's opportunity set.

The organizational structure defines the roles of participants and the resources available to carry out the tasks identified with the roles. The structure defines jurisdictional boundaries, lines of communication, and authority. It is the basic structure in which transactions and decision processes take place. Roles are always incompletely specified.

Cyert and March, in their pioneering work, emphasize the concept of standard operating procedures (SOP). In order to reduce transaction costs in decision making, the group develops SOPs. These are generally accepted rules of thumb for the operation of the firm. The SOPs are political solutions reconciling the difference in perceptions and preferences

of the various participants. As long as the goals of members of the group are satisfactorily met, the SOPs are retained. If target goals are not met, participants have an incentive to search for new patterns of behavior that better meet the targets. SOPs vary from complex decision trees to rules for delegating authority and rules for responding to other firms' actions. Knowledge of a firm's SOPs could provide the information for simulation models to predict firm behavior.

The control system consists of the rewards and punishments associated with decisions and effort. The contingencies are embedded in compensation, promotion, and retention practices as well as in peer approval. The ability of top management or leaders to impose their goals on the organization is a function of the effectiveness of the control system. The external environment, organizational structure, and the control system shape each member's opportunity set.

Individual objectives and beliefs determine how members respond to their opportunity set within the organization. Beliefs and goals are not independent, however. They are influenced by a socializing process within an organization, which may be a significant influence on patterns of behavior.

Firms

The basic concept of the firm is that of a bureaucratic organization of members with disparate goals and individual discretion, within limits, operating under conditions of great uncertainty. It is hypothesized that variation in behavior and performance will be associated with the size and structure of firms, with the goals of the participants, and with the discipline imposed by the external environment.

A dynamic framework must also consider the interaction of the firm with the external environment. The extent of participant discretion is affected by the capacity of the firm and its participants to shape or protect themselves from the external environment. It is assumed that investments will be made to influence both the regulatory system and the market. Through collective action or custom, classes of participants acting across an industry insulate groups and practices within firms from the discipline of the market—for example, unions establish work rules, accountants have standards, and many decisions are based on industry-wide standards.

Galbraith (1967) argues that large-scale enterprise is a technological imperative. Investments pay off over a long period, and in order to protect such investments the technostructure attempts to reduce uncertainty by obtaining a measure of control over the external environment through vertical integration and contracts for inputs and products, influencing demand by advertising, stimulating government purchases, sheltering the firm from the uncertainty of capital markets through retained earnings obtained in oligopolistic markets, and influencing the regulatory system.

Williamson provides an insightful analysis of the incentives for firms to integrate vertically and thus grow. He emphasizes uncertainty of markets and the incomplete nature of contracts. Bringing an activity within the firm deals with problems of information impactedness, among others. Williamson argues this phenomenon is more important than the technological imperative in explaining firm size.

Firm growth is a powerful dynamic force if the objective is to gain control over the external environment. The greater the size, the greater the capacity for political and market influence. If size also allows greater firm member discretion, and individual rewards to managers are related to size, the incentive is reinforced.

The concepts of organizational slack—payments to firm members in excess of what is required to maintain the organization, as developed by Cyert and March, and X-inefficiency (Leibenstein, pp. 76, 79), roughly the deviance of a firm's performance from that which could be accomplished within its external opportunity set—represent phenomena and lines of inquiry of great significance for system performance. For example, based upon his analysis, Leibenstein concludes: "1) the cost of a commodity is not independent of the price of the commodity; 2) except in extreme circumstances firms do not minimize costs; 3) cost of production has a tendency to rise toward the price level; and 4) there is no production function independent of the environment of the firm and the history of the firm" (1976, pp. 492–93).

Organizational slack, however, has important economic functions. In an uncertain world, firms make many mistakes and must deal with unforeseeable situations. If firms went out of business with every adversity, the economy would be in chaos. Hirschman argues that loyal or inert customers contribute to

slack and that slack is necessary to allow firms time to recoup from temporary poor performance.

Households

Household behavior can be analyzed within the same general framework as other organizations. A multiperson household, for example, will develop specialized functional roles. Typically, this will include a purchasing agent with perceptions and preferences differing from other members. Transactions between the purchasing agent and other members will lead to an acceptable set of SOPs for purchasing, and specific products will become embedded in other SOPs and individual techniques. An example of a consequence of this fact is that prices of products may vary within a range without response. That is, there will be a price threshold. Thus, an existing price represents a unique point on a kinked demand curve. And when a price change is sufficient to cause a reevaluation of related SOPs, a new purchase pattern resistant to change will develop. Thus, a change in price can result in a shift in a household's demand curve. Household behavior is influenced by advertising and other promotion practices and by the mix of products made available. Endogenous preferences are part of the dynamics of the system.

Government

We are interested in governments as mechanisms for the articulation of preferences and as bureaucratic organizations for implementing policy. The conceptual framework for organizations generally applies. Governments are made up of participants with goals of their own operating under conditions of great uncertainty. Elected officials are uncertain about the preferences of voters and uncertain about the consequences of their own actions. Votes often carry little information. Thus, the external environment of a governmental unit often provides a very nonspecific discipline. The discipline is similar to that of stockholders over a large corporation. The economics of political influence is an important aspect of preference articulation. Elected officials have limited capacity to impose their preferences on the bureaucracy. Implementation of policies and programs depends upon the effectiveness in shaping the opportunity sets of the participants. The effectiveness of government depends heavily on the ideology and strategy of the agency.

Government and markets are joint mechanisms for articulating preferences. Government produces the regulatory system shaping the opportunity set of firms and households. This determines what has to be taken into account by participants. The regulatory system sanctions a pattern of private power including facilitating and limiting collective action. In this sense, markets deal only with solved political problems, and the market is an instrument of the regulatory system.

The Market

The genius of the market as a social institution is that it provides a mechanism for collecting and summarizing an enormous quantity of idiosyncratic information about the environment and preferences in an easily understood form (prices), which at the same time carries incentives to produce and conserve to the participants of the system. The political economic problem is to institute the regulatory system in such a way that price carries the information and incentive, as consistent as possible with preferences for system performance and the reality of the environment. Two marginal comments: (*a*) market power is the ability to influence opportunity sets and is a function of the market structure and political influence, and (*b*) trading is usually between agents who have some discretion.

The Food System

Meeting the objectives of the NC 117 project requires (*a*) a description of the food system, (*b*) some understanding of the evolution of the system, (*c*) a means of identifying performance, (*d*) a capacity to design policies and programs to achieve specific performance norms, and (*e*) a means of predicting the consequences of specific programs and policies. This section includes brief comments related to these tasks and a few conceptual and practical issues.

First, we have a conceptual problem in defining the U.S. food system and, thus, the scope of the project. I propose a broad definition, not suggesting that it is possible to direct research to the whole, but to provide a context for the inquiry.

Start with the concept of a systems model which would provide a simplified description of that part of the world that has an interdependence with production, distribution, and use of food in the U.S. The striking reality is that much of the world's political economy and ecology influence, or are influenced by, these activities. An industrialized food system uses inputs which originate in every corner of the globe. U.S. food input and product markets are affected by public policies and organizational behavior of many countries. Chemicals used to produce U.S. food enter the ecological system of the entire world and deplete world resources. Many multinational and conglomerate firms supply inputs and process and market food.

Policy Design

To evaluate alternative policies, it is necessary to predict the way in which the policy will alter the opportunity sets of the relevant participants, the consequence that will have on behavior, and in turn on performance. This means attention must be paid to the details of the policy design.

The implementation procedures must be included in policy design and evaluation and must be based on predicted responses of both public and private participants. For example, developing a workable approach to protection from toxic substances in food depends upon knowledge of SOPs of users and behavioral interactions between inspectors and users.

Policy making is an evolving process. It is necessary to develop a feedback and monitoring process for the system. Developing performance indicators is critical to the process, and the design of the indicators is a major conceptual task. For a useful discussion of problems in translating global notions about performance of the food system into policy relevant indicators, see Jesse.

Evolving Structure

A key to projecting changes in food system organization is an understanding of the processes of firm growth, including incentives for vertical integration. Many hypotheses might be suggested. An especially intriguing question relates to the concept of opportunistic behavior. What is the consequence for the structure and performance of the food system of market participants operating from different ethical standards?

The recent interest in farm structure would be informed by an understanding of the changing structure of the food system. What has been taking place is the shift of functions from the farm firm to nonfarm firms, many of them large conglomerates. Of the total value added in the U.S. food system, probably less than 10% is accounted for by on-farm activities.

The complexity of the evolving structure is illustrated by the observation that the largest grain handler in the world (Cargill Grain) operates the largest beef feeding organization (Caprock Industries) which sells to the second largest beef processor and wholly owned subsidiary of Cargill (MBPXL) which markets a large proportion of its product through contractual agreements to the largest fast-food chain (McDonald's) (adapted from Richardson).

Preference Articulation

Preference articulation refers to the processes by which preferences are expressed and taken into account. This includes the ability to satisfy preferences within an existing opportunity set and influence the content of future opportunity sets. The effectiveness of the food system as a mechanism for preference articulation is the key question about the system performance. The effectiveness of preference articulation is a function of the behavior of firms in searching both the preference and physical opportunity sets, the behavior of households in transmitting information and influence, and the responsiveness of government.

Our attention is directed to problems where the system as instituted is either a barrier to effective preference articulation or fails to facilitate preference articulation. These include the basic micro-macro problems where individuals following their own immediate interests lead to long-run consequences inconsistent with the preferences of the group. The missing institution may be the lack of a mechanism for the collective expression of preferences. For example, the local grocery store may have lost out in competition with the supermarket because no mechanism existed for customers to express their preferences for the option to have the store available. Food reliability is a major dimension of performance for the food system, but problems exist in

articulating preferences for the option to have adequate food available at a future date and for food safety. Many dynamic sequences seem to result in outcomes inconsistent with all (or most) participants' preferences. The demise of some light density rail lines serving rural areas is an example. The institution for collective action is missing. Such problems often are identified as market failure, but might better be identified as institutional failure.

Practical policy analysis needs to be directed to the diagnosis of such situations and the identification of the missing institutional mechanism for effective preference articulation.

Equity or justice is a particularly important dimension of performance and must be included in analysis. It is not possible to articulate preferences for equity through the market. Many conceptual problems exist in designing policies to reflect preferences for justice, including the development of performance indicators.

Vertical Coordination

Vertical coordination is a special problem of preference articulation. The issue is the effectiveness of coordination of supply decisions with demand. It deals with the sufficiency of price as a carrier of information and incentives and the behavior of participants in strategic positions. For example, the SOPs and interaction of purchasing agents, merchandisers of large retail chains, and marketing agents of food manufacturers determine to a large extent the characteristics and variety of food products offered to consumers. These practices severely limit the effective access of new products and products from new and small firms. The institutional mechanism for consumers to articulate a choice for a different set of choices is missing.

The cycles in hog and beef supplies and prices are another illustration of the problem in the U.S. food system. There is no evidence that the variation in supplies is related to variations in preferences for these products. The institutions are missing that could provide coordination of current production decisions of producers as a group with future demand. The missing institution may be a system of forward-deliverable contract markets.

Productivity and Costs

If large firms have the capacity to influence prices and members have independent goals and discretion in the firm, then it could be expected that costs would tend to rise to the level of prices. If groups can improve their immediate returns or security by restricting inputs or output and have a collective capacity to do so, productivity will be reduced and costs increased. These phenomena contribute to both lower productivity and a cost-price spiral. This follows from the behavioral model of the firm.

Galbraith and Williamson argue persuasively that large firms seek to protect themselves from uncertainty and that this is necessary. And slack is necessary for survival. But small firms also seek the same protection and for the same reasons. They attempt to accomplish the needed protection from the uncertainty associated with unfettered competitive markets through government programs, collective action, and contracting. Careful analysis is necessary in developing policy to squeeze out "X-inefficiency" to assure that the long-run consequences and trade-offs are accurately assessed.

The argument often is made that regulations reduce productivity and increase costs. Often the regulation simply shifts costs among participants. And thus, the question is, whose preferences should count? However, regulations also often impose unintended and unnecessary costs—the regulation is inappropriately designed. Participants may seek regulation to facilitate collective action that results in reduced output. Union work practices are an example. The missing institution is a mechanism to achieve equity objectives which does not reduce productivity.

Inflation

Inflation is a major problem and NC 117 has been asked to address the issue of the relationship of inflation to the food system. If inflation is a general rise in prices, and firms and groups behave as indicated in the discussion of productivity and costs, and the supply of money is responsive to the demand for money, as it must be, then industrial concentration and the organization of the food system can cause inflation, especially if firm managers are opportunistic. An understanding of inflation thus

requires an understanding of organizational behavior and market structure.

A Final Comment

A practical argument often is made that it is not possible to include behavioral variables in analysis because it is not possible to obtain the data. This is a monumental problem. My argument is that for policy-relevant analysis, we at least need to make assumptions about behavior based on the best data we can get. A conceptual framework that includes behavioral variables generates hypotheses which can at least partially be tested by observable actions of the participants.

Just as bounded rationality is a fact of life in organizations, it is also true for analysts and theorists. We have to recognize the very limited capacity we have for understanding and predicting the behavior of such a complex system. The most unrealistic assumption of all is that of the omnipotent analyst.

The Permanent Income Hypothesis under Rational Expectations

John F. O. Bilson

It is unfortunately true that the most noticeable legacy of the permanent income hypothesis for applied economic research has been to provide a convenient justification for the appendage of a lagged dependent variable to multiple regression equations. Even apart from the fact that a significant coefficient on the lagged dependent variable may reflect serial correlation in the regression errors or the presence of a partial adjustment mechanism instead of the permanent income-forecasting mechanism, the procedure is not a valid test of the permanent income hypothesis because the probable size of the coefficient on the lagged dependent variable is not defined from a prior analysis of the time-series process generating the actual income series. As Muth (1960) demonstrated, the adaptive expectations approach will only provide optimal forecasts of permanent income if the actual income series is generated by a first-order, moving-average process. If this is the case, then the permanent income hypothesis implies a direct cross-equation restriction between the value of the parameter in the time-series process and the value of the coefficient on the lagged dependent variable.

The object of this paper is to describe this manner of testing the permanent income hypothesis and to apply the approach to estimation of the aggregate consumption function in the United States, the United Kingdom, and the Federal Republic of Germany. Although the approach is applied to estimates of the aggregate consumption function, it is readily applicable to demand functions for particular commodities.

The Rational Expectations-Permanent Income Hypothesis

The most common definition of permanent income[1] is that constant level of income (or consumption), y_t^p, which satisfies the intertemporal budget constraint

$$(1) \quad A_t + \sum_{i=0}^{\infty} [E_t\, y_{t+i} - y_t^p](1 + r)^{-i} = 0,$$

where A_t is the predetermined stock of savings at time t; y_{t+i} is the expected level of real income in period $t + i$, conditional upon the information available at time t; and r is the (constant) real rate of interest at which the household can both borrow and lend. This specification assumes that the household is infinitely lived, that there is no difference between lending and borrowing rates, and that the term structure of interest rates is flat. Relaxing these assumptions complicates the analysis but does not alter any of the important conclusions of the model.

The important characteristic of this definition is that permanent income is constructed so as to be expected to remain constant over the planning horizon. In other words, if the information which becomes available in period $t + 1$ does not alter the expected value of income in any of the future periods, then the estimate of permanent income will not change. This implies immediately that the only factor that will cause permanent income to change will be new information about the expected future path of actual income. This point may be formally stated by solving equation (1) for the change in permanent income:

John F. O. Bilson is an assistant professor of international economics at the University of Chicago, and a research economist with National Bureau of Economic Research, Inc.

This is a summary of a paper entitled "The Rational Expectations Approach to the Consumption Function—A Multi-Country Study," scheduled for publication in the *European Economic Review* in 1980.

[1] The revival of the analysis of permanent income begins with the work of Sargent, 1977, and Hall, 1978. The present exposition is based upon the discussion in Flavin (1978b) who points out an error in Sargent's derivation and demonstrates an essential equivalence between the theoretical models of Sargent and Hall.

$$(2) \qquad \Delta y_t^p = \frac{r}{1+r}\Delta A_t + \frac{r}{1+r} \sum_{i=0}^{\infty} [E_t\, y_{t+i} - E_{t-1}\, y_{t+i-1}](1+r)^{-i}.$$

The term inside the square brackets may be decomposed into the change in the expected value of income in period $t + i$, $E_t\, y_{t+i} - E_{t-1}\, y_{t+i}$, and the expected change in income conditional upon the information set of period $t - 1$, $E_{t-1}\, \Delta y_{t+i}$. Since $E_{t-1}\, \Delta y_t^p = 0$, equation (2) implies that

$$(3) \qquad \Delta A_t = - \sum_{i=0}^{\infty} E_{t-1}\, \Delta y_{t+i}\, (1+r)^{-i}.$$

The term on the right-hand side of this equation is the negative of the change in the stock of wealth that arises from the anticipated future changes in actual income. The equation states that this value will be equal to the change in the stock of assets from $t - 1$ to t. It is through this pattern of saving or dissaving that the household maintains a constant expected level of permanent income in the face of anticipated variation in the flow of actual income.

This does not mean, however, that the actual estimate of permanent income is constant or, for that matter, even stable. Substituting equation (3) into equation (2) yields the general expression for the change in permanent income,

$$(4) \qquad \Delta y_t^p = \frac{r}{1+r} \sum_{i=0}^{\infty} DE_t\, y_{t+i}\, (1+r)^{-i}.$$

In equation (4), the operator DE_t denotes the change in the expected value and it is defined by $DE_t\, y_{t+i} = E_t\, y_{t+i} - E_{t-1}\, y_{t+i}$. Equation (4) views the household as receiving new information in period t about the expected level of income in period $t + i$ and then adjusting its estimate of permanent income by the present discounted value of these changes in expected value. The equation also illustrates the fundamental feature of the RE-PIH model emphasized by Hall: since permanent income will change only in response to new information, the change in permanent income will be white noise. In other words, under rational expectations it should not be possible to predict the change in permanent income, and hence the induced change in consumption, on the basis of previously available information because this information already will have been discounted into the estimate of permanent income at the time that it becomes available. The idea that demand functions based upon the notion of permanent income are more stable than those based upon actual income is not, therefore, an implication of the theory.

In order to complete the theory, it is obviously necessary to describe the process through which households form their estimates of future income. Although a number of approaches to this issue are possible, the discussion here will be restricted to the assumption that the information set is restricted to the past history of the actual income series.[2] In addition, the time-series process generating actual income is assumed to be the infinite order, stationary, invertible moving-average process,

$$(5) \qquad \Delta y_t = \sum_{i=0}^{\infty} \psi_i\, u_{t-i}.$$

Equation (5) is a useful forecasting equation for the RE-PIH model because the new information is restricted to the current innovation, u_t, and because the update in the expected change in income in period $t + i$ is simply defined by $DE_t\, \Delta y_{t+i} = \psi_i\, u_t$. Because the level of income in $t + i$ can be written as $y_{t-1} + \sum_{j=0}^{i} \Delta y_{t+j}$, the change in the expected level of income in period $t + i$ is simply the sum of the updates in the expected changes from t to $t + i$:

$$(6) \qquad DE_t\, y_{t+i} = \sum_{j=0}^{i} \psi_j\, u_t.$$

Substituting this result back into the definition of permanent income in equation (4) yields the following expression relating the change in permanent income to the innovation in actual income:

$$(7) \qquad \Delta y_t^p = \alpha\, u_t.$$

The α coefficient, defined to be $\sum_{i=0}^{\infty} \psi_i\, (1+r)^{-i}$, may be interpreted as the present discounted value of the moving average coefficients. The size of α depends upon the extent of the serial correlation in the actual income series which, in turn, depends upon the structural characteristics of the macroeconomic system. In the Keynesian unemployment model, for exam-

[2] See, for example, the empirical sections of the papers by Barro, Bilson and Glassman, Hall, Flavin (1978a) and Sargent.

ple, where the changes in actual income in response to an innovation in aggregate demand are assumed to be positively correlated through the multiplier mechanism, the α coefficient is likely to be greater than unity. There is no presumption, then, that the variance of permanent income will be less than the variance of actual income although, as an empirical matter, this is likely to be the case.

Equation (7) carries two empirically testable propositions. First, if consumption is proportional to permanent income, then consumption should respond only to unanticipated changes in actual income. Again, the reason for this result is that any anticipated change in actual income will already be discounted into permanent income and, hence, into consumption expenditures. Second, the marginal propensity to consume out of unanticipated income should be approximately equal to the α parameter estimated from the time-series model. If this condition is not met, then the household will violate its anticipated intertemporal budget constraint and consequently will not be able to maintain the current level of consumption expenditure.

There are a number of ways in which tests of the RE-PIH model can be run.[3] In the following, one set of tests based upon aggregate consumption data for three developed countries—the United States, the United Kingdom, and the Federal Republic of Germany is presented. For a number of reasons, these tests should be considered as illustrative. The most glaring weaknesses include the fact that the consumption measure includes the consumption of durable goods and that the forecasts of actual income are not based upon all readily available information.

Empirical Tests of the RE-PIH Model

The first step in the empirical analysis is to estimate the time-series process generating real per capita disposable income. In this analysis, disposable income is defined as gross national product less government expenditure rather than the more usual gross national product less taxes. The neo-Ricardian definition of disposable income was considered to be more consistent with the RE-PIH assumption that the household completely discounts anticipated future tax liabilities so that tax finance and deficit finance have symmetric effects on disposable income. Second, this measure of disposable income avoids problems associated with certain large tax rebates that induce spurious correlation in the conventional disposable income time series process.

The estimated models are presented in table 1. The theoretical model, with its infinite order, moving-average (MA) process, is implemented by truncating the MA process at lag 10. It is clear that this model "overfits" the sample data in each sample. Many of the estimated coefficients are not significantly different from zero. Each of the models do, however, exhibit a characteristic pattern of negative MA coefficients in the first four lags followed by positive coefficients at the longer lags. This implies that the typical reaction to an income innovation is for the initial shock to be followed by further income changes in the same direction before a reversal is felt.

In conjunction with equation (7), the estimates presented in table 1 can be used to estimate the α coefficient of the permanent income model. Since the α coefficient is also a function of the rate of interest, the estimates of the α parameter are given for a range of values of the real rate of interest, which is expressed in units of percent per quarter. Because the interest rates are quarterly real rates, the normal range would be from zero to 2%.

	Interest Rate (%)		
Country	0.0	2.0	4.0
Germany	0.1112	0.2706	0.4306
	(0.10)	(0.09)	(0.08)
United Kingdom	0.1422	0.2977	0.4240
	(0.08)	(0.07)	(0.06)
United States	0.1903	0.3814	0.5375
	(0.10)	(0.09)	(0.08)

The standard errors of the estimated coefficients are included in brackets beneath the estimates. It is interesting to note, in this regard, that the α parameters are estimated precisely despite the apparent imprecision of the estimates of the time-series models. The implication is that the long-run response to an innovation is quite stable despite the fact that the adjustment to the long-run state is not precisely estimated.

The estimates of the α parameter have the

[3] In Bilson, a number of other tests of this model are presented. Other approaches are contained in the references cited in footnote 2.

following interpretation: at a zero real rate of interest, a one dollar increase in income of \$1.00 should be associated with a 10¢ to 20¢ increase in permanent income. Because the income reversal takes place in the future, higher interest rates discount the future decline in income relative to the current increase and hence the α parameter increases with the rate of interest. In addition, because the future income is more uncertain than the current income, higher discount rates also are associated with more precise estimates of the α coefficients.

To test the RE-PIH model, the equation

$$(8)\quad \Delta c_t = \beta_0 + \beta_1\, uy_t + \beta_2\,[\Delta y_t - uy_t] + \beta_3\,\Delta w_t + \beta_4\,\Delta s_t + v_t$$

is estimated. In this equation, Δc_t is the change in per capita consumption expenditure, uy_t is the innovation in real disposable income per capita, Δw_t is the change in the real wage, and Δs_t is the change in the real stock price index. The real wage is included as a relative price variable. Higher real wages are expected to increase consumption expenditure by inducing the household to increase its supply of labor to the market and to substitute toward market goods in its household production function. Alternatively, if the wage index is considered as a measure of "expected prices," the real wage may represent the relevant relative price of current consumption goods relative to future consumption goods. The real stock price index is included in the consumption function as a measure of wealth. Hall demonstrates that this variable is related significantly to consumption expenditure in the United States, and Barro includes real corporate profits as an alternative proxy variable. It is necessary to include these variables in the regression equation to prevent a spurious significant coefficient on the anticipated income term because of the cyclical movement in real wages.

The main interest in the regression is, however, in the first two terms. Under the RE-PIH hypothesis, the coefficient on the unanticipated income term, uy_t, should not be sig-

nificantly different from the estimate of α from the time-series process. Also, the coefficient on anticipated income, $\Delta y_t - uy_t$, should not be significantly different from zero, because anticipated changes in income should not influence permanent income in the current period. The results of the estimation are presented below:

GERMANY: 1964:I–1978:IV

$$\Delta c_t = \underset{(10.64)}{22.8907} + \underset{(0.07)}{0.1883}\, uy_t + \underset{(0.07)}{0.0779}\,(\Delta y_t - uy_t) + \underset{(656.4)}{3074.4}\, \Delta w_t + \underset{(679.0)}{1747.8}\, \Delta w_{t-1} + \underset{(109.3)}{119.21}\, \Delta s_t + v_t$$

−0.19 0.28 0.21 −0.21

In these results, the t-statistics are included in the parameters below the coefficient estimates. Before proceeding to the tests of the RE-PIH model, it is interesting to note that there is a strong real wage effect on consumption in each of the countries under study. In addition, either the current or first lag of the change in stock prices also appears to be significantly related to the change in consumption expenditure. These results may be taken to support the classical form of the consumption function relative to the Keynesian variant.

From the regression results, a new set of α coefficients may be obtained from marginal propensity to consume out of unanticipated income. Under the assumption that the distribution of the α coefficient is normal, the difference $(\alpha_1 - \alpha_2)$, where α_1 is the estimate from the time-series analysis and α_2 is the estimate from the regression model, will also be normally distributed. If the two estimates are independent, the variance of the difference is simply the sum of the variances of the two estimates. The compatibility of the two estimates may then be compared by constructing the standard normal variable $(\alpha_1 - \alpha_2)/(\alpha_1 - \alpha_2)$, where $(\cdot)$ is the sample standard deviation, and testing if this difference is significantly different from zero. The values of the standard normal variable are given below for a range of values of the real rate of interest:

Interest Rate	Germany	United Kingdom	United States
0.0	−0.57	−2.20	−0.34
2.0	0.79	−0.65	1.39
4.0	2.07	0.71	3.10

In general, these results are supportive of the RE-PIH model. In each case, the statistic is not significantly different from zero for interest rates in the range of zero to 2%. Only in the case of the United Kingdom is the real rate of interest that would be compatible with the hypothesis greater than 2% per quarter, and this result could be due to sampling variation.

The second implication of the model—that anticipated income changes will not influence consumption—is also strongly supported in the samples from Germany and the United Kingdom. In these cases, the coefficient on the anticipated income term is both small and not significantly different from zero. In the U.S. case, however, the data deals a rejection to the null hypothesis since the coefficient on anticipated income is relatively large and sig-

nificantly different from zero. In fact, in the U.S. case, the evidence suggests that the appropriate income measure is actual, rather than permanent, income.

Conclusion

The object of this paper is primarily methodological in the sense that it has attempted to point out the implications of the permanent income hypothesis for the estimation of aggregate demand functions rather than attempt to provide a set of "best" estimates of the aggregate consumption function. For this reason, the actual empirical results must be considered as tentative illustrations rather than as econometric evidence upon which definitive conclusions can be based. In particular, the evidence is weakened by the failure to develop a complete model for forecasting actual income and by the failure to distinguish between different types of income and different types of consumption goods. Despite these and other obvious weaknesses, the results are generally supportive of the approach and they suggest that the application of rational expectations methodology to the estimate of demand functions with permanent income may be a fruitful and exciting extension of current applied economics.

Post-Keynesian Economics and Agriculture: Discussion

Bruce Gardner

These three papers are about as diverse as can be in a session on a particular topic. The topic, post-Keynesian economics and agriculture, is already broad because of uncertainty about exactly what post-Keynesian economics consists of. The session is even broader because one of the papers, Shaffer's, is somewhat tenuously related to post-Keynesian economics and another, Bilson's, does not have anything in particular to do with agriculture.

Work labelled as "post-Keynesian" seems to fall in two categories. One category continues into uncharted territory on lines of inquiry initiated, or believed to have been initiated, by Keynes. Although I have some trepidation about the political connotation of the term, this may be called left-wing post-Keynesianism. It is exemplified by Joan Robinson's writings. The Chichilnisky and Taylor paper seems to fall into this category. The second category constitutes to some extent a reaction against Keynesian ideas. It may be called right-wing post-Keynesianism. It is exemplified by the rational expectations approach to macroeconomics. Bilson's paper is interesting in that it falls into the latter category, yet provides new ammunition for certain Keynesian positions as against counter-Keynesian claims. This serves to illustrate the limited usefulness of the left-wing and right-wing labels.

The Chichilnisky and Taylor (C&T) paper is clearly Keynesian in that the income-expenditure relationship expressed in the simplest "Keynesian cross" plays a central role in the model. From this point, matters quickly become for me much less clear.

I have two main concerns that leave me unwilling to accept the models of the C&T paper as appropriate for either positive analysis or policy recommendation. First is a lack of a clear statement of the microfoundations of the model, and the dubious nature of the microfoundations as I understand them. Second is the lack of empirical support for the model.

On the first point, I would have been extremely grateful to have had a concise list of the assumptions made in each of the two models, a list of the endogenous and exogenous variables, classified as such, and mathematical statements of the basic behavioral equations and identities used. An example of my difficulties in these areas is the following statement from late in the paper: "Largely to avoid unilluminating mathematics, labor and capital are assumed to be freely shiftable between the sectors, and fixed coefficients for these inputs characterize technology." There is real economic content here, not just mathematical complications to be so casually swept away. I would like to have known if these or other assumptions also lie behind the earlier model of figure 1, or, if such assumptions are irrelevant to that model, why this is so. Generally, a mathematical statement of the model would almost surely be illuminating because it would necessarily lay out in detail which variables were assumed to be functions of which others, and which were exogenous, left out, or redundant.

Like most agricultural economists, I suppose, I am most comfortable with supply and demand as the basis for economic modeling of a sector of an economy. Consequently, the most natural multisector models are those based on aggregation of sectoral supply and demand equations, i.e., Walrasian general equilibrium models or the corresponding two-sector neoclassical general equilibrium model used, for example, in the Rybczynski paper that Chichilnisky and Taylor cite. What C&T must sell, in this view, is the notion that the supply-demand approach should be replaced by the Keynesian model for purposes of sectoral policy analysis, particularly for agricultural policy. To this end, it would have been illuminating, I think, to contrast the consequences of exogenous events such as import

Bruce Gardner is a professor of agricultural economics at Texas A&M University.

controls, decreased production of agricultural products, or a shift in demand for nonagricultural products in the Keynesian model compared to the consequences of analogous shifts in a neoclassical model. For example, in the case of import restraints, a neoclassical approach would involve considering the elasticity of domestic demand for and supply of agricultural products, and income effects and factor-market adjustment in the nonfarm sector. The Keynesian model involves the *ex ante* trade deficit and required savings in the agricultural sector, and the effects of agricultural prices on demand for nonagricultural products. Similarly, the effect of a production shortfall depends first and foremost on elasticities of demand in standard theory, and C&T's discussion in terms of savings and demand effects in nonagriculture seems to elevate second-order effects to primary roles. Can these different approaches be made to mesh? If not, is the implication that the behavioral parameters that we usually think central in analyzing the effects of, say, a tariff on sugar, really irrelevant?

In their final paragraph, C&T say: "The question is whether or not the models capture slices of likely economic response. Our view is that they do. . . ." This expression of opinion, unbuttressed by reference to any empirical work, is the entire justification offered by the authors in favor of adopting their models as tools for policy analysis. Much more is needed, to my mind, to argue for adoption as a policy tool a model in which the Keynesian cross applies to a single sector, nonagricultural prices and wages are exogenously fixed, and there is no supply function in its usual neoclassical sense for either agricultural or nonagricultural products.

Minor points: (*a*) in C&T's second model, the absence of land as a factor of production in A is striking. When land is included, the relative share of labor in agriculture is lower than in nonagriculture, contrary to C&T's treatment of nonagriculture as the capital-intensive sector. (*b*) The discussion of inflation seems quite ad hoc in that the model contains no financial sector, governmental activity, taxes, or money. Indeed, it is not clear that the general price level is determinate in this model—any level of the CPI would be consistent with equilibrium. (*c*) It is not clear why the models pertain to a "semi-industrialized" economy as opposed to a fully or nonindustrialized economy. The idea must be: The more plausible assumption for such an economy is that nonagricultural output is determined by demand, while its price is fixed. But why?

Turning to the Bilson paper, the only important weakness I can attribute to the author is his decision to present it at a session on agriculture. The idea that permanent income may in fact be a much less stable variable than one might at first suppose is an interesting one. The implication that an individual's consumption follows a random walk under rational expectations provides a potentially useful way to place consumption in the stochastic simulation models of growth of farm firms that one sees in the literature. The treatment of consumption expenditures in almost all of these models is so inadequate as to be scientifically scandalous. Bilson's approach might well provide a vehicle by which these sinners may reform.

On the Shaffer paper, my main complaint is that despite its subtitle, the progress toward a conceptual framework is too slight. We have concepts in plenty but too little framework. The E-B-P (environment, behavior, performance) sequence does not provide enough structure to illuminate one's thought processes about the political economy, at least not mine.

My ability to understand what the paper is driving at was hindered at times by a lack of precision in definition of terms. The "environmental situation" is a basic concept in the paper, as is "opportunity set," but neither the distinction between them nor the content of either was made clear enough. Early in his paper, Shaffer says: "Participants in a political economy exist in an environment situation which is their opportunity set." Soon thereafter we read: "The environment can be thought of conceptually as overlapping opportunity sets." And then "his opportunity set is governed by the external environment and the internal structure of the organization and his positions."

Similarly, the concept of "articulating" preferences is introduced as follows: "Individuals articulate preferences, that is, seek their goals. . . ." But later, in discussing preferences for the option of having a local store available, articulation is made parallel to expressing preferences. And then, in discussing equity, the problem of articulating preferences is explained in terms of "policies to reflect preferences for justice." Both these ideas are combined in the definition: "Preference articulation refers to the processes by which prefer-

ences are expressed and taken into account." Finally, in the section on vertical coordination, articulation appears to consist of coordinating preferences. In the end, it is quite unclear whether articulating preferences means to express them, to have policies reflect them, to coordinate them, to seek their satisfaction, or some combination of these activities.

This looseness of thought defeats the attempt to make progress toward a conceptual framework. In addition, the ambiguities create difficulty in assessing specific assertions made in the course of Shaffer's general tendency to diagnose the source of various problems as the lack of an appropriate institution. He says: "Problems exist in articulating preferences for the option to have adequate food available at a future date. . . . It is not possible to articulate preferences for equity through the market." One's reaction to these claims depends on what the term "articulate" is taken to mean.

I would like to introduce some final general remarks about this session with Shaffer's statement that his paper's "connection with post-Keynesian economics is that of a common belief that existing paradigms are inadequate. . . ." This view, and Shaffer's subsequent discussion, seem to me to illustrate both a desirable and an undesirable aspect of this kind of writing. The desirable aspect is the intellectual risks taken, encouraging us to entertain new ideas and to question old ones. The undesirable aspect results from what Johnson calls "the tempting thought that revolutionary new truths about the economic system can be intuited by rejecting existing ideas about it" (1971, p.3). The result is that one too often finds authors writing under the post-Keynesian label who are not interested in providing organized facts, analysis, or research results, but instead are telling us what we ought to be doing in place of our current research; in short, they are preaching. Our authors today are to be commended for avoiding this approach, for the most part. (As a discussant, it is of course acceptable for me to preach as much as I wish.)

To sum up: in my search in these papers for ideas for improving my understanding of the economics of agriculture or food policy analysis, I came up empty-handed. Shaffer is too vague, Chichilnisky and Taylor too empirically unsubstantiated, and Bilson too unrelated to agriculture. Nonetheless, some of the ideas put forth could well lead, in future development, to improved understanding and analysis.

Post-Keynesian Economics and Agriculture: Discussion

G. Edward Schuh

The three papers we have heard are most challenging and interesting. Since they are quite different in their perspectives, they do not lend themselves to an integrated discussion. Hence, I will discuss each of them separately.

Shaffer's paper, although focused on an important topic, is both frustrating and disappointing. The title of his paper suggests that he will take initial steps toward a conceptual framework that presumably will do a better job of describing the food system than we have had in the past, and which will give us a sounder and more comprehensive basis for evaluating the performance of the food system. In point of fact, however, there is little theory in the paper, or little which in my judgment takes us very far in terms of having a more realistic or more general description of the food system.

Shaffer's paper is perhaps too ambitious for the time and *Journal* constraints of this session. As a consequence, certain sections read like a series of random ideas with no theme. In fact, most readers will probably find it difficult to keep the theme of the paper in mind as they read it. The paper also has a sufficient number of statements so elliptical in nature as to be of little analytical value as to suggest that it was squeezed down from a larger paper.

But let me be more positive. As I understand this paper, and as I understand North Central Regional Project 117, the objective is to understand important dimensions of the U.S. food system that have been neglected in the past. Participants in that project presumably believe that neoclassical economic theory is too narrow a framework to understand that system. Hence, they have attempted to broaden the analytical framework.

That is an admirable goal, and certainly is to be encouraged. Neoclassical economics is obviously not the only road to the truth. Moreover, our job as social scientists will not be done until we understand what goes on in households as well as in firms, until we understand why governments do what they do, and until we understand the behavior of organizations such as labor unions and other such entities that do not fit neatly into the categories of firms, households, and government.

Despite my respect for this goal, I have some serious reservations about the routes that are currently being taken to attain it. Moreover, I fear that we are engaged in much too much ad hoc-ery, and are investing all too little in developing a solid analytical or conceptual work. In this context I would like to make four points:

(*a*) First, to understand the behavior of some entities, it would be useful to start with simple behavioral axioms, work through the implications of these in terms of predicted behavior, and then test these predictions with data. Although many of us will challenge the postulates of conventional theory, few of us do what sound scientific procedure suggests we should do—formulate, examine, and test alternative hypotheses about behavior and performance. Perhaps the best example of this is with the government sector. All too often we either assume government behavior to be exogenous, or we assume that it is irrational. Having been part of the government sector myself, it seems clear to me that it is very responsive to price and other economic stimuli. Similarly, having been a part of government, I obviously believe it is sheer foolishness to assume that governments are irrational.

(*b*) Second, we should make better use of well-accepted concepts we now have available to us, such as concepts of market failure, externalities, free riders, and public goods. These concepts can help us to understand a great deal of the imperfections we see in the market place. Unfortunately, we have a tendency to give lip service to these concepts, but we seldom go much beyond that.

G. Edward Schuh is a professor and head of the Department of Agricultural and Applied Economics, University of Minnesota.

(*c*) I sadly fear that we do not draw sufficiently on the other disciplines of the social sciences in extending our economic models. For example, political science has a great deal that can be of use in developing a theory of political economy. Similarly, many of the attempts to move away from the narrow confines of neoclassical theory take us onto ground already well-trod by the sociologists. Parson's "A Theory of Action" was an attempt at developing a more general theory of behavior than that provided by neoclassical economics. Have we really tried to take advantage of that theory? Or of other developments in sociology?

My concern is that there is little reflection of these other bodies of theory in Shaffer's paper, or in the other work of NC 117, for that matter. In fact, the membership of NC 117 is made up entirely of agricultural economists. It is this failure to draw systematically on these other disciplines that gives much of the work in this area its ad hoc character.

(*d*) Finally, we could make much greater use even of recent extensions of neoclassical theory. Again, there has been little attempt in agricultural marketing to draw on the new household economics to explain household behavior, as formulated by either Becker or Lancaster. Yet both of those bodies of theory would appear to have a great deal to offer in understanding phenomena that NC 117 is designed to understand.

To conclude, let me emphasize once again the importance of work in this area. To make much progress in filling the gaps in our knowledge, however, it seems clear to me that we need to make greater use of the other social science disciplines. If we were to make that effort, we might make an important step in reintegrating the social sciences into a more unified whole. That, too, has to be one of our goals.

The paper by Chichilnisky and Taylor deals with an important and until now relatively neglected set of issues—the connections between agriculture and the rest of the economy and the constraints these connections imply for economic policy. Their paper gives us a formal model by which we can interpret and analyze the rather large body of structuralist literature. Such formalization forces us to make our assumptions rather explicit, and facilitates the testing of that theory.

I would like to make six comments on this paper:

(*a*) The supply side of their model is deficient. The analysis is very much demand motivated, and goes into some detail on that side. The authors compare their results to those of the structuralist school in Latin America. One of the reasons for that similarity is that they are similar to the structuralists in their neglect of the supply side.

(*b*) In the first part of their paper the authors assume that food and most raw material demands are price inelastic. That implies that they are dealing with a closed-economy model. For some purposes that is useful. But for many countries one has to be concerned about the realism of this assumption. More important, in later parts of the paper the closed-economy assumption is relaxed, but it is not clear that the assumption about price elasticity has been changed.

(*c*) This model leads to what the authors consider to be a structuralist model of inflation. I question whether this model is adequate to imply anything about inflation. If it is, I would like to have this shown more carefully. My impression is that the model does not have enough equations to explain the price level. It is a model which can explain shifts in the terms of trade, but is it not sufficient to explain the price level.

(*d*) In the latter part of the paper, it is assumed that agriculture is the labor-intensive sector of the economy. That, of course, was the naive view for some time. We now have ample evidence of the capital intensity of agriculture, even in fairly primitive societies. It would be useful to work the analysis through with the opposite assumption. If the authors were to do this, while giving more attention to the demand implications of an open economy, some of their "puzzles" might well disappear. More specifically, the absorptive capacity of the agricultural sector might not be so limiting, and the responses to standard policy ploys might not be so perverse.

(*e*) In expanding the supply side of the model, I would encourage the authors to take account of what we are learning about agricultural development in terms of human capital and induced technical change. By this means we will be able to avoid going down the road of the naive growth models, models that became so abstract as to become sterile.

(*f*) Finally, the failure of the authors to tie their analysis to other papers in the field is rather disappointing. For example, they might benefit from a perusal of Flander's paper some

ten years ago, "Agriculture versus Industry in Development Policy: The Planner's Dilemma Reexamined."

Bilson's paper is different from the other two in that it reports on a rather straightforward econometric estimation of the parameters for the consumption function, using the rational expectations approach. I found it to be an insightful and rewarding paper.

An important contribution of this paper is the contrast it draws with the more straightforward permanent income approach to the specification of the consumption function. Unfortunately, the empirical tests of the model lead to ambiguous conclusions. Therefore, one is left with some rather deft econometric results, but with the state of our knowledge not having been advanced very far.

In discussing this paper, I would like first to make a comment, and then to ask a question. Hopefully, the question will lead to more general discussion of some of the implications of the rational expectations model.

My comment has to do with a possible reason for the rather anomalous statistical results. It would seem that it is rather naive to restrict K to be zero so that all of the information needed to forecast future income is assumed to be contained in the past history of the series. In fact, I fail to see how this procedure is greatly different than the distributed lag specification of the conventional consumption function, and I fail to see how one has done a great deal more than to test a particular specification of a distributed lag model. Moreover, why would not consumers be using a full-fledged economic model to make their forecasts of future income? And why would not this expectation model need to be fully specified so that we can take better advantage of what we already know about the economy?

My second comment is a question. Assuming that the world is rational expectationist, what does that imply for policy makers? If a policy maker is attempting to define a reserve policy for agriculture, for example, or to set target prices for agricultural commodities, how does he do it differently, or what difference does it make, if rational expectations are an appropriate approach to the world? I hope we can focus on this issue in the discussion.

Finally, I would like to challenge my agricultural economics colleagues to begin to test this new theory in their attempts to understand the agricultural sector. At one time agricultural economists were on the cutting edge in adopting alternative theoretical models and in adopting new quantitative tools. But to date we have virtually ignored the permanent income hypothesis. Let us hope we do not do the same thing with rational expectations. I suspect that this perspective has a great deal to offer in terms of improving our forecasts and in terms of understanding some of the cyclical behavior that characterizes the agricultural sector.

Agricultural Development: The Key Link in China's Four Modernizations Program

Robert F. Dernberger

Mao Tse-tung, the source of legitimacy for the radical leaders of the left-wing of the Chinese Communist Party, died in September of 1976. The radical left-wing leaders were arrested and removed from their positions of power within the month following Mao's death and a new, post-Mao leadership coalition under the control of the right wing slowly emerged during the course of 1977. Thus, in early 1978, Chairman Hua Kuo-feng's "Report on the Work of The Government," delivered to the National People's Congress, announced that the solution of China's economic problems would now take precedence over the ideological objectives of Mao's social and political revolution (Hua, 1978). To solve those problems, the National People's Congress adopted the Ten-Year Plan (1976–1985) for the Development of the National Economy, which Hua had summarized in his report. Utilizing themes originally put forth by Chou En-lai in the early 1970s, this Ten-Year Plan was to be the first stage in achieving the modernization of China's agriculture, industry, defense, and science and technology—the four modernizations—by the end of the twentieth century.

Ever since Hua's speech which announced the plan for achieving the Four Modernizations, Chinese leaders and press reports have emphasized continuously that "agriculture is the foundation of the national economy," and that "the development of agriculture at a high speed is the most important guarantee of success in modernization" (FBIS, 25 Oct. 1979). Furthermore, in the post-Mao spirit of respect for the facts, it is admitted that "China has difficulties in feeding the urban population and in ensuring a rational development of industries using farm products as raw materials" (FBIS, 6 Mar. 1979). According to a *Renmin Ribao* (6 Mar. 1979) editorial, "modernization will quite simply be out of the question if this state of affairs continues." Few Western specialists on China's economy, and I am sure none at this panel, would disagree with the argument that the modernization of China's agriculture, while not a sufficient, is a necessary condition for the modernization of China's economy.

The magnitude of China's agricultural development problem, the extent to which the Chinese have solved the agricultural problem over the past three decades, and the probability of their solving the agricultural problem in the near future, however, are topics of major disagreement among Western specialists. I have presented my position in this debate on more than one occasion (Dernberger). Inasmuch as Tang is presenting a paper on the trends in Chinese agricultural production in 1952–78 at this panel, while Lardy is a discussant, I gratefully yield to these two knowledgeable and capable specialists for their evaluations of the empirical record of China's agricultural development experience in the past. In this paper, I will devote my attention to what I consider an even more crucial determinant of China's success in achieving the modernization of China's agriculture in the future: the package of policies the new, post-Mao leadership has adopted to achieve the modernization of China's agriculture.

These policies, of course, were adopted by the new, post-Mao leadership on the basis of their own understanding of the empirical record of agricultural development over the past three decades, especially that of the more recent past. Western specialists who estimate and interpret this past record more favorably can claim the new, post-Mao leadership is motivated by the need to present the policies of their predecessors as failures; those whose estimates and interpretations provide us with a more pessimistic picture can argue the Chinese mean what they say when they claim

to be seeking "truth from facts." Whatever their motives, the Chinese evaluation of their past record of agricultural development that has been made available to Western specialists over the past two years depicts the emergence, especially over the past decade, of an ever worsening situation.

For example, a study of grain production between 1965 and 1976 in 2,196 production teams in "various" provinces was reported at a conference sponsored by the Institute of Agricultural Economics of the Chinese Academy of Social Sciences at the end of 1978 (Guangming Ribao, 7 Dec. 1978). According to that report, yields had increased at an average annual rate of 2.8%, while costs had increased at an average annual rate of 4.0%. Furthermore, the value of a day's labor had declined from 0.70 yuan to 0.56 yuan over the same period. A major source of the increase in costs, as the estimates presented by Tang should indicate, is the rapid increase in the use of purchased inputs in the decade after 1965. Thus, inasmuch as output prices were not increased over the period between 1965 and the mid-1970s, it is not surprising to learn that the survey of grain production in 2,196 production teams in 1976 revealed that production costs (probably inclusive of labor costs), plus taxes, exceeded the state's purchase price by 10.6%. Or that a survey of cotton production in 302 production brigades in 1977 revealed production costs which exceeded the state's purchase price by 2% (FBIS, 26 Oct. 1979).

Although the reports of the State Statistical Bureau show that the total gross value of agricultural production (in current values) increased at an average annual rate of 6.2% between 1952 and 1978, grain output increased at an average annual rate of only 2.6% and the average per capita grain distribution was no greater in 1978 than two decades earlier in 1957.[1] Of more immediate importance, grain output did not grow between 1975 and 1978 and, therefore, grain availability per capita from domestic production was declining. Thus, when the new, post-Mao leadership came into power, these inherited developments in agricultural production not only were a serious threat to their ability to maintain the standard of living, they also threatened their ability to use agriculture products, a major source of export earnings in the past, for the purpose of increasing export earnings to pay for producer goods imports. It is not surprising, therefore, that a major concern of the new, post-Mao leadership over the past two years has been the introduction of new policies for achieving the modernization of China's agriculture.

China's New Agricultural Program

Our purpose in this brief paper is not to analyze the details of each of these new agricultural policies, nor to analyze the dynamics of their evolution as an integrated and complete program for the modernization of China's agriculture. In the course of 1978, the Chinese increasingly became aware that the mere arrest of the radical leaders and their followers would not eliminate China's fundamental economic problems and that, in light of these problems, the plan for 1985 was unrealistic. Thus, in Hua Kuo-feng's "Report on the Work of the Government" to the second session of the Fifth National People's Congress in the summer of 1979, he reported that a new five-year economic plan for 1981–85 would be drafted and ready for adoption at the next National People's Congress, and further, that the next three years, 1980–82, would be devoted to putting the Chinese economy back onto the path of sustained economic growth (Hua 1979).

Throughout 1979, a great many arguments have appeared in Chinese publications and many experiments are being tried out in a search for the proper set of institutional and policy changes that will put the Chinese economy back onto the path of sustained economic growth. According to Vice-Premier Ku Mu in October of 1979, "We have become convinced of the need to completely reform our economic institutions and economic policies from the top down to the lowest level, but how to reform them is a difficult problem and will take some time."[2] Any attempt to spell out China's new agricultural policy program at the present time, therefore, would be premature. On the other hand, the various agricultural policies that have been advocated and the institutional changes in agriculture that have been tried over the past two years do provide us with

[1] Average annual rates of growth were calculated by the author on basis of total values for 1978 and 1952. The 1978 totals are from FBIS, 3 July 1979; the 1952 totals are from State Statistical Bureau, 1960.

[2] Quote is from the author's notes from a briefing and interview given by Ku Mu for the delegation of American economists in Oct. 1979.

ample evidence of several basic themes of the new agricultural program currently evolving in China. The purpose of this paper is to present a summary of these basic themes and to assess their implications for the modernization of China's agriculture.

Perhaps the most surprising development has been the retention and open advocacy by the new leadership of many elements of the major program advocated and implemented by their predecessors: the Tachai or Advanced County Campaign. That campaign, especially its method of implementation during the first half of the 1970s, is now openly criticized. This is not true, however, for those components of the Advanced County Campaign which were designed to achieve a significant technological transformation of China's agricultural production. These included the innovation of new varieties and cropping patterns; the increase in irrigated area and use of chemical fertilizers; the mechanization of agriculture; extensive farmland reconstruction; the electrification of rural China; and the development of rural, small-scale industries for the production of cement, chemical fertilizer, iron and steel, agricultural machinery, and electric power. These policies were a major feature of Chinese agricultural development efforts in the first half of the 1970s.

On 5 October 1979, the Central Committee of the Chinese Communist Party issued a lengthy policy document on "Some Questions Concerning the Acceleration of Agricultural Development" that was adopted by the fourth plenary session of the Eleventh Central Committee of the Chinese Communist Party.[3] Of the twenty-five policies and measures for developing agriculture this document advocates, five repeat policies were being pursued in the early 1970s for the technological transformation of China's agriculture. Despite these similarities in policies per se, however, the new program for the modernization of China's agriculture represents a thorough and necessary "rationalization" of the technical ingredients of the Advanced County Campaign as it was carried out in the past.

As for the policy of developing new seeds and cropping patterns, the practice of every unit having an experimental plot is questioned as a waste of land; experimental plots can be more efficiently managed in communes which specialize in the production of new seeds. It is now admitted that inter-cropping and more multiple cropping have not raised annual yields everywhere, but have done so only under certain conditions. The practice of each unit producing a variety of crops to increase the degree of self-sufficiency or diversification is also found to be a source of inefficiency; specialization in those crops best suited to the climate and soils of the local unit are now argued as a better means for providing higher yields. For the purpose of facilitating the more scientific breeding of seeds and adoption of proper cropping practices and patterns, the Chinese have recently begun to survey and catalog soils.

In farmland reconstruction, the practice in the past of mobilizing farm labor for these projects is criticized for the extent to which it ignored the opportunity costs of labor, and examples are cited where yields in crop production and the income of peasants declined as a result. Some of the projects in the past also have been criticized for the poor design, poor results, or ineffectiveness in increasing yields, or their high costs in terms of scarce construction materials.

In irrigation, the rapid expansion of the irrigated area in the past is criticized on the basis of the low level of efficiency of the various irrigation projects, the extent to which they wasted resources, the extent to which their design capacity is not realized, and the extent to which mechanization is concentrated on a limited amount of irrigated land. In other words, a considerable increase in yields due to increased irrigation can be obtained by significantly increasing the efficiency of the existing irrigation system. As for new irrigation facilities, a major problem continues to be the North China Plain, and involves two major irrigation projects. Although somewhat dormant in the 1960s, considerable work has been done on the Yellow River project since 1949. The Chinese now admit, however, that the two most serious problems faced by the project have not yet been solved: silting and excessive alkalinity. Specialists are now being organized and a conference was held to propose solutions to these problems, solutions which are necessary if the potential of the Yellow River is to be harnessed for irrigation. The second major irrigation project is yet to be

[3] The full text of this document, as adopted by the fourth plenary session of the eleventh Chinese Communist Party Central Committee is reproduced in FBIS, 25 Oct. 1979. A preliminary draft of this document had been adopted by the third plenary session, Dec. 1978 and had been circulated, discussed, and modified in the intervening nine months.

tackled; tapping the better quality and more voluminous flow of water in the river system of Central China, especially the Yangtze River, and bringing that water to North China. Concern has been expressed, however, over the costs of such a project and the possible consequences of diverting water from the Yangtze to the North. The Chinese are now reconsidering the alternative routes and the costs and benefits of the project.

The problems uncovered in the attempts to electrify the rural areas are related to China's present economy-wide energy shortage. Agriculture undoubtedly will be given a high priority as a result of the readjustment of priorities in the current reevaluation of the national economic plan; and the electrification of the rural areas will remain as an objective of China's agricultural modernization program. Nonetheless, the inefficiency in the generation of electricity by the rural power stations and the efficiency of its present allocation and use have been questioned, especially in regard to the generation of electricity at much lower costs by means of large-scale, hydro-electric power stations and the use of electric power at much higher levels per unit of output in the rural, small-scale industries.

The mechanization of agricultural production gained great prominence in 1978, but the Chinese have had second thoughts about not only the feasibility, but the wisdom of mechanization. Articles in the Chinese press have argued that the objective of increasing yields calls for land-saving, or augmenting, technical change, while mechanization is a labor-saving, or augmenting, innovation. Thus, given the recognized inability to supply the machines required to meet the original targets for the mechanization of China's agriculture, mechanization should be emphasized in the less labor-abundant areas, i.e., on state farms in the Northeast. As for the production of agricultural machines, they should be produced in complete sets, and should be produced in factories which specialize in the production of their various components. To have agricultural machinery produced in short runs in factories spread throughout the countryside is simply too inefficient and costly.

Discussions in the Chinese press over the past year which concern the "rationalization" of industrial policy emphasize the extent to which many industrial plants are suffering financial losses, have a low productivity of labor, use excessively high levels of scarce resources per unit of output, and produce poor quality output. These criticisms are held to be especially true for many rural, small-scale, industrial plants. To correct for this problem, it is argued that unless they improve their profitability and reduce the input costs of their production, these inefficient plants should be closed down.

The expanded use of chemical fertilizer is the one element of the Advanced County Campaign's program for the technical transformation of China's agriculture that has not been criticized. Perhaps the reason for this is that much of the increase in yields achieved before 1975 can be attributed to the significant and rapid increase in the availability and use of chemical fertilizer. The rapid expansion of production and use of chemical fertilizer, therefore, continues to be a major objective of the new leadership.

As a whole, of course, the "rationalization" of the program for the technical transformation of China's agriculture in the Advanced County Campaign adds up to a significant change in policy introduced by the new leadership. Moreover, these changes, to the extent they are made effective in being implemented, should improve the probability of China's success in achieving agricultural modernization; not only by eliminating much that is wasteful or of limited use in increasing yields, but also by concentrating on those innovations which, in the historical experience of other countries, do achieve that objective.

An interest in the historical experiences of other countries relates to another major change in the new leadership's search for a solution to China's agricultural problems. In the past, the source of technical innovations and institutional and policy changes in agriculture was sought within the context of China's own experience. In order to pursue the objectives of self-reliance and participation by the masses, most communes throughout rural China experimented with low-level technical, institutional, and policy innovations. Those innovations the leadership selected as successful on the basis of their results alone, without a careful statistical analysis of cause and effect or costs and benefits. They were adopted as models to be copied in nationwide campaigns. The new, post-Mao leadership not only recognizes that innovations and policies that work in one region of China may not be appropriate to dissimilar environments found

throughout the rest of the country, but they also stress the need to learn the truth from facts by means of statistical analyses which ascertain if the results of an innovation are indeed what they are claimed to be and if they are worth the costs. Moreover, the experiences of those countries that have achieved successful agricultural modernization and high yields are being studied as a source of possible institutional and policy changes in China.

This search abroad for new knowledge as a basis for policy making and the greater emphasis placed on empirical testing for policies that are implemented should increase favorable prospects for China's future agricultural development. The new leadership's modification of the priority given agriculture in the state's allocation of investment funds should be of more direct benefit. Following the agricultural crisis at the end of the 1950s, the Central Committee of the Communist Party adopted a fundamental change in development priorities in August, 1962, recognizing that China's agricultural problems would not be overcome quickly or by means of institutional reorganization and greater labor inputs alone. Instead of agriculture receiving a relatively low priority compared to heavy and light industry as in the 1950s, henceforth agriculture was to be treated as the "foundation" of China's economy and economic development strategy. As a result of that decision, investments in agriculture and in industries producing inputs for agriculture were increased. Faced with those same agricultural problems almost two decades later, the Chinese now claim that the earlier shift in priorities was not enough. Thus, investment in agriculture was increased from 10.7% to 14% of the state's capital construction investment in the 1979 state budget, and it is claimed that the government will increase the agricultural share even more in the future (FBIS, 3 July 1979). In addition, in the process of the current readjustment of the production and investment plans for the industrial sector, those industries producing goods for use in the agricultural sector undoubtedly are to be given an even higher priority than in the past.

Economic, Social, and Political Problems

Compared with China's "rationalization" of changes in emphasis and priorities in its program for the technical transformation of its agriculture, the change in the incentive mechanism to achieve the desired results represents a rather sharp break with the past. In many campaigns, the cadres at the county and commune level were exhorted to mobilize the peasants to undertake the innovations described above. The whole thrust of the new agricultural policies, however, is an explicit rejection of this approach. Quite simply, the institutional and incentive structure being created in agriculture by the new, post-Mao leadership is for the purpose of motivating the individual peasant—or the low-level unit of production of which he is a member—to achieve high and stable yields because of the direct material benefits to himself. County and commune level cadres are to provide the necessary guidance and control, while the leaders of the Party will provide policy guidelines; but those leaders are relying heavily on the peasants themselves to get the job done.

In decision-making, production, and income distribution, the post-Mao leadership has put great emphasis on making real the promise of the new Constitution that the basic unit in agriculture will be the team. The commune and brigade level administrations remain important for administrative and large-scale investment and health, education, and welfare purposes, but the team has gained considerably greater freedom to determine how it will utilize the resources at its disposal for achieving the modernization of China's agriculture. To correct for problems that are said to have been common in the past, the ability of the team to elect its own team leader is to be restored and the resources of the team are not to be requisitioned by higher level authorities without "fair" compensation.

As for the distribution of income, the new, post-Mao leadership has devoted considerable attention to reinterpreting Marx to show that individual material incentives directly related to the quantity and quality of work done by the individual and income differences based on skill and effort differentials are consistent with the laws of economics in a socialist system. As in the past, the peasant's income from work done in the collective sector is based on the work points earned for that work, the value of the work point determined on the basis of the production of the collective unit as a whole. Nonetheless, work points are to be task specific and not awarded on the basis of time periods or on the political merits of the individual.

Although approximately 80% of the commune's farm land is still included within the state plan, production teams and individual households are free to determine their income earning activities in subsidiary activities.[4] To encourage their use of these opportunities to increase production of commodities that meet the needs of both the state sector and consumers, the leadership also has reinterpreted Marx to show that maximizing incomes is a desirable objective in a socialist economy and does not represent a restoration of capitalism. Furthermore, considerable encouragement is being given to specialization in these group and individual sideline activities. The new leadership also has tried to remove the ideological stigma attached to market activities, and rural and urban markets for these subsidiary products have grown rapidly over the past year. After its initial attempt to control transactions and prices in these markets, the government removed controls on most of the commodities traded on these markets because the administrative burden proved to be too great.

The most important agricultural products, of course, remain within the state plan and are sold to the state at fixed prices. Nonetheless, to provide greater material incentives for securing increased production and state procurements of these products, a significant price increase for state procurements of agricultural products was introduced in the summer of 1979. In addition, a much greater increase in price is paid for above-quota deliveries. The national average price increase for procurements of grain was 20%, 25% for oils and fats, 15% for cotton, and 26% for pigs. The average price increase for above-quota deliveries was 50% for grain and oils and fats and 30% for cotton (FBIS, 25 Oct. 1979). Finally, provincial and lower level authorities have been given the authority to reduce taxes to lighten any existing "excessive" or counter-productive tax burdens in the areas under their jurisdiction.

This summary statement of the producer-incentive policy changes introduced by the new, post-Mao leadership should be sufficient to indicate the extent to which the emphasis has been shifted from the county- and commune-level cadres to the peasants themselves as the instruments for achieving the modernization of China's agriculture. Equally important, these new policies also indicate the extent to which the new leadership believes that these price and income-earning incentives will achieve the desired results.

Future Problems and Prospects

To a Western trained economist, many of the above institutional and policy changes in China's agricultural program would appear to improve greatly the chances of achieving higher yields. Yet, it is not too difficult to think of problems the Chinese will encounter as changes in policy are implemented. Despite these new policies and even though the technical aspects of the advanced county campaign have been rationalized, the attempts to develop new seeds, increase irrigated area, increase the use of chemical fertilizer, and continue the electrification and mechanization of agricultural production will not be easy tasks to accomplish. These problems in the technical aspects of the modernization of China's agriculture, however, have been analyzed extensively in the published literature. Even given the serious nature of the inherited characteristics of China's fundamental agricultural problem, however, I believe that it is the nontechnical or economic, social, and political aspects of the new agricultural policies that will be the most important determinant of the long-run success of the current program to modernize China's agriculture.

For example, the new leadership claims the encouragement of low-level decision making and initiative, material incentives, and markets is consistent with the economic laws of socialism and do not necessarily represent a capitalist restoration. Nonetheless, Chinese press reports already have attacked those who have taken advantage of the new policies to decentralize the basic unit of production below the level of the production team; who have taken advantage of the encouragement to engage in subsidiary and income-earning activities, which threaten growth in the collective sector activities within the plan; and who have taken advantage of the encouragement to participate in market activities in order to engage in exploitation and speculation. Thus, in its search for greater efficiency and higher

[4] During their visit to China in Oct. 1979, the delegation of American economists was told by provincial and commune officials that 80% of the land in the commune was included in the state plan that was sent down to the communes. The targets in this plan included acreage to be planted in various crops, yields, and state procurements.

yields, the new leadership must continually be on guard that new policies do not erode the basic principles of socialism and eventually lead to a capitalist restoration in the countryside. In other words, the new leadership easily can find itself throwing the "clean baby out with the dirty bathwater."

Even assuming that the peasants' behavior and motives remain within the bounds of socialist values, however, the new policies will have consequences which will put severe strains on the objectives of China's version of socialism. After three decades of advocating greater equality in the regional or sectoral distribution of income, the existing inequalities in the standard of living within rural China and between the rural and urban areas are both obvious and considerable.[5] What is important is that the major thrust of the new agricultural policies—decentralization of decision making, productivity related material incentives, specialization, and a greater role for income-earning activities in the market—will tend to produce an even greater inequality of income. Lardy's study of the Chinese fiscal system shows how the central government's control of the budget process has been used in the past to redistribute some revenues from the richer to the poorer provinces so as to achieve a modest closing of the gap between relative levels of regional incomes. On the other hand, current experiments in the fiscal system, again for the purpose of creating material incentives to encourage local initiative, call for an increase in the share of locally collected revenue to be retained and spent at the local level.

As for the attempt to reallocate resources by means of physical allocations within the plan, current readjustment of the plan undoubtedly will give greater priority to agriculture (rural areas) and less to industry (urban areas). Yet, the material incentive mechanisms being implemented in both the rural and urban sectors and the increase in the role of markets for the provision of commodities to convert these money incomes into real consumption presents a challenge to the planners by reducing, to some extent at least, their control over the sectoral and regional allocation of resources. Thus, a more equitable distribution of income could well be one of the victims of "putting economics in command" for solving China's agricultural problem.

Even when the new incentive system did lead to a significant adjustment in the urban-rural inequalities by means of a significant increase in the prices paid for agricultural products delivered to the state, urban industrial workers were promised this price increase would not be passed on to consumers. However, because of losses suffered from buying agricultural products at prices above the retail price, the state raised retail prices. Yet, the decline in real income for the urban industrial worker would not only create considerable urban discontent, but also would threaten the hoped for increases in productivity from the wage increases that had been granted to industrial workers. In the end, the industrial worker will receive both his wage increases and a 60 yuan subsidy a year to offset the increase in retail prices for agricultural products. However, the average peasant, who earns an annual income of less than 100 yuan in many provinces of China, will receive an annual increase in income of approximately 8 yuan because of the increase in the price paid by the state for agricultural products. This explains why, during my recent visit to China, an agricultural official in Shensi answered my question as to what single change in agricultural policy was needed most for securing an increase in agricultural production by immediately replying, "another increase in purchase prices."

Although the widening of the gap between the rural and urban standards of living represents a direct rejection of a principal theme of Maoism, I believe the growing regional inequalities within the rural sector itself as a result of the new agricultural policies may present the Chinese leadership with an even greater problem. In some areas of rural China the peasants' standard of living is relatively high, even higher than that of an average industrial worker, while in many areas the peasants are poor. Mao, of course, was not the champion of all the Chinese peasants. Rather, his appeal was to China's poor and the agricultural policies he advocated were designed to improve their relative standard of living. This,

[5] For example, the delegation of American economists (Oct. 1979) was told that per worker (industry) annual income in Shanghai Municipality in 1978 was 780 yuan as against a distributed income of 270 yuan per capita in the communes. The same ratio was reported to be 693 to 68.3 yuan in Shensi Province and 600 to 94 yuan for Kiangsu Province. When the comparison is made more valid by converting urban workers' average incomes into their urban per capita equivalent, as was done by the authorities in Shensi Province, the comparison of worker and peasant consumption on a per capita basis in 1978 yields a ratio of 389 to 124.8 yuan. Finally, the ratio of the average per capita peasant income in the richest compared to the poorest county in Kiangsu Province in 1978 (the province with the highest gross value of agricultural output of any province in China in 1978) is 220 to 50–60 yuan.

I believe, was the crux of the "two-line struggle" of the past three decades; to benefit the poor or to benefit the most productive. In short, I believe the policies of the new, post-Mao leadership for the modernization of China's agriculture, which obviously benefit the most productive, are seriously challenging the objectives of Mao's socialist revolution. That challenge, I believe, is the greatest problem faced by the current campaign for the modernization of China's agriculture.

Trend, Policy Cycle, and Weather Disturbance in Chinese Agriculture, 1952–1978

Anthony M. Tang

Utilizing the estimated input-output time series for 1952–1978 developed in a larger study on the agriculture of the People's Republic of China, I attempt in the present paper (*a*) to quantify and analyze the secular behavior of total factor productivity of the sector; (*b*) to test and analyze the changing impact of weather on productivity in light of such developments as socialist reorganization of the countryside, massive water control, and introduction of new biological, chemical, and mechanical inputs within the context of Peking's successful "weather-proofing" claims; and (*c*) to isolate and attempt a crude measure of the cyclical swings in productivity attributable to policy or political cycles in the PRC. The total factor productivity index (*TFPI*) is residually calculated from an aggregate production function whose coefficients are assigned values from the estimated base-period (1952–57), relative factor income shares. (Aggregation is arithmetic on both the output and input sides.) The method is conventional enough and raises a number of familiar issues. Following Solow (p. 312) whose seminal work popularized the methodology, we make no attempt "to justify what follows by calling on fancy theorems on aggregation and index numbers. Either this kind of aggregate economics appeals or it doesn't." *TFPI* is obtained by dividing the gross value of agricultural output (*GVAO*) index by the aggregate input index.

The Chinese Development Strategy

In order to analyze Chinese agricultural performance in perspective, it is necessary to present first the country's development strategy and to spell out how agriculture is supposed to relate itself to the design. In the PRC, the Chinese Communist Party regards itself as the supreme repository of truths. The values and goals of its leadership generally displace those of the people. In a capsule form, these values are aptly summarized in a metaphor attributed to A. Bergson: To the party leadership, bread is an intermediate product; steel is the final good. Bergson's reference was to the Stalinist strategy of economic development—a strategy embraced by Peking's leaders as they assumed power in 1949. A concrete expression of the embedded values can be found in the oft-repeated aspirations of the Chinese leaders, present and past, of turning the PRC into "a modern, front-ranking power" (a superpower, if you will) by no later than the end of the present century.

The power-oriented value and goal imperatives, together with the clear sense of urgency attached to their attainment, dictated a development strategy best described as the "maximum-speed selective growth under austerity" and required a "command economic system" for implementation. While selectivity is associated with the modern heavy industrial sector, whose absolute size is the preponderant determinant of national power on contemporary world scenes, the command system es-

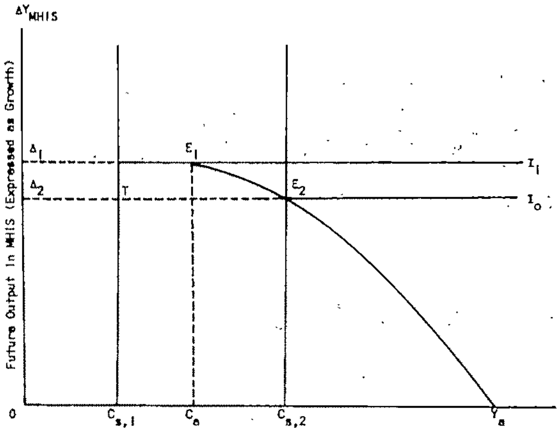
Anthony M. Tang is a professor of economics at Vanderbilt University.

The author is indebted to Rendigs Fels and R. C. Blitz for their helpful comments and wishes to express his sincere appreciation for excellent graduate research assistance of Thomas R. Gottschang of the University of Michigan. The Mellon Foundation support via Michigan's Chinese Economic Studies Project, under the direction of the late Alexander Eckstein, is gratefully acknowledged. Much of the basic conceptualization and data development was accomplished during the author's visit in Ann Arbor while on leave from Vanderbilt.

In the interest of space, the input-output time series are not presented in this paper. They are available to interested readers upon written request to the author. These estimates are, in turn, supported by some fifteen tables with explanatory notes and source references covering some forty pages. The detailed notes are designed to enable readers to retrace and recalculate every single entry in the tables. For such information, the readers are referred to the author's forthcoming monographic study to be published by the Center for Chinese Studies of the University of Michigan.

chews markets and prices in important ways, preferring to allocate critical economic resources administratively (i.e., the hard way).

The "bread-steel" metaphor makes it clear that the role of agriculture is to support priority (selective) industrialization with (extracted) savings articulated by real resource transfers in the form of food (the principal wage good), labor, raw materials, and exportable farm products. Recent statements from Peking remind us of the critical dependence of China's industrialization on agriculture. A special feature article in *Beijing Review* pointed out that agriculture contributes about 85% of the people's means of subsistence, 70% of the raw materials needed by light industry, 40% of materials needs of all industry, and "a considerably large part of our financial revenue" (Shi, p. 15). Where agriculture failed to meet the full resource transfers required by the priority industrial sector for maximum growth, the agricultural sector became the bottleneck acting as a drag on industrialization. In such a case, agriculture, though hierarchically inferior, becomes—in a planning and operational context—indistinguishable from industry. To develop agriculture is to develop industry. On the other hand, the effective bottleneck may lie outside agriculture with limitations in the foreign trade sector, the productive capacity of the capital goods sector, or the absorptive capacity of priority industry.



Note: The term "net" refers to output available for agriculture's own consumption and extracted savings by the state, after first meeting current resource requirements and wage good requirements for current production in *MHIS*. Current resource requirements include those covering depreciation for steady-state operation in *MHIS*. For simplicity, it is assumed implicitly that there is balanced trade via some state-stipulated set of terms of trade between agriculture and industry in current terms. Thus, extracted savings by the state bear on $\Delta MHIS$.

Figure 1. Maximum-speed selective growth model

By adapting elements from the Fisherian optimum saving and growth model, the Lewis-Ranis-Fei two-sector model, and the Chenery-Strout-MicKinnon-type constraint growth model, we offer in figure 1 a graphic representation incorporating all the salient features of the Chinese development strategy. The sectoring is between agriculture (the dominant branch of the economy where saving and resource mobilization for investment in industry must impinge) and the modern heavy industrial sector (*MHIS*) whose growth lends substance to the power-oriented development strategy. The horizontal indifference curves of the planner (who acts for the political leaders) follow directly from the "bread-steel" preference symbolism. Current consumption enters our model as a constraint set by some floor, subsistence standard (as at $C_{s,1}$ or $C_{s,2}$). This floor may be relaxed without altering our analysis to deal with the concept of an optimum wage and consumption in a maximum-speed growth context of Chiang and Fei in which the effort-productivity implications of the wage-consumption policy in a command economy are considered. (This is to say, location of C_s affects positively Y_a.) The intertemporal transformation curve (Y_aT) links up present agricultural resource transfers with future output growth in the priority *MHIS* sector.

The planner's object is to maximize his utility intertemporally within the planning horizon. (Beyond that horizon, after China achieves the power status it seeks, consumption enters the planner's social welfare function.) Given a present agricultural output OY_a (as defined in the note to fig. 1) and curve Y_aT for transformation, if $C_{s,1}$ is the floor for agriculture's own consumption of its output, the planner's optimum is at E_1, yielding Δ_1 for *MHIS* growth in the future period, actual consumption of OC_a (with ample margin over the set floor), and savings extracted from agriculture for investment in *MHIS* equal to Y_aC_a. Here, the binding constraint on industrialization is outside agriculture, and for the time being the state can neglect agriculture and concentrate investment on *MHIS* exclusively. In passing, we note that this was the case with Stalinist Russia in the 1930s (Tang 1968).

Placing the consumption constraint at $C_{s,2}$ (as with a larger agricultural population but about the same output as before), the planner now finds the effective bottleneck to his industrialization drive inside agriculture. His realizable maximum growth in *MHIS* is Δ_2. Own consumption for agriculture is held to the floor level at $C_{s,2}$. And forced savings, $Y_aC_{s,2}$, represents the maximum extraction. With agriculture as the bottleneck, the planner attempts to develop the sector by first emphasizing mobilization of indigenous resources of low or no opportunity cost to industry, exploiting traditional production possibilities and eventually exhausting them after increasingly severe diminishing returns. The development program takes on complexities not present earlier. All branches of the economy are now interdependent and compete for the planner's attention.[1] Basically conflicting dual policy requirements (output growth and maximum extraction) are imposed on agriculture. Bureaucracy and command structure grow accordingly. Even more so than before, direct quantitative controls are preferred as in rationing basic consumer goods (a Chinese practice since 1955).

In an attempt to deal with these problems, or "contradictions" in Marxian lexicon, efforts are made to find nonmaterial substitutes for incentive in order to raise output without incurring increased consumption (viewed as a cost by the planner). Inasmuch as China's industrialization has been agriculture-constrained as is clear from earlier empirical testing (Tang, 1968) and from Peking's recent own reckoning,[2] the country's preoccupation, especially under Mao, with "radical experiment"—a predilection as we shall argue later responsible for Peking's policy cycles—is quite understandable. So was Mao's singular concern with the problems of government and party bureaucracies, as symbolized by his concept of "permanent revolution" to keep the governing apparatus "renewed." At the opposite end from radical courses of action, Peking has shown a willingness to compromise high principles of socialism and nationalism. In the singular case of Hong Kong and Macao (where Peking virtually insisted that Britain and Portugal retain the territories as colonies) the bending of these principles is severe indeed. The overriding importance attached by Peking to its $2 billion-plus net annual foreign exchange earnings through trade, remittances, and its banking and commercial operations in the two Western colonies, attests at once to the preeminence of growth-related values vis-à-vis the competing ideological and nationalistic considerations. The latter, like consumption, will assert themselves one day. Within the relevant time horizon, they too are best treated as constraints, rather than as arguments in the objective function. The Hong Kong-type policies serve to raise the transformation curve (through more efficient conversion of China's agricultural surplus into capital goods and technology for industry than can be achieved without the markets and services of these colonies) by pivoting upward around the point Y_a; clearly there are limits to such policies. Thus, it is unthinkable for Peking's post-Mao leadership to bring back capitalist practices to the point of undermining the *raison d'etre* for a Communist regime.

The virtue of the command system lies in its recognized efficacy in mobilizing resources for the attainment of some single-minded social objective. Efficiency and finesse in using the resources thus mobilized are not among its strong points. Balassa's recent summary analysis of comparative growth performance makes the point abundantly clear. Socialist economies have savings ratios about twice those of the advanced industrialized western nations (Japan excluded) but showed overall rates of growth that are no higher. At the same time, those market economies (mainly, in East Asia including Japan) with savings ratios comparable to the Socialist rates have enjoyed growth rates more than twice the rates in the Soviet-type economies. Interestingly enough, within the Socialist bloc the apparently great differences in degree of decentralization do not seem to make much difference. However, what needs to be restated in this connection is that, to the large Socialist countries for whom power-aspiration and the command approach make sense, the relevant standard has to do with growth of *MHIS* (including the armament and space industries). In these terms, their

[1] This argument casts doubt on the conventional China scholar's view that in the First Five-Year Plan, Peking unwittingly embraced the Russian model's "industry only" bias, discovered the mistake a few years later, and switched in the early sixties to "agriculture as the foundation." The switch had to do with a shift in emphasis from reliance on traditional inputs to modern inputs centering on chemical fertilizers. The move follows simply from diminishing returns under traditional production possibilities. No reordering of priorities as such was suggested. In fact, Peking's current orthodoxy considers the First Plan period and the readjustment years of 1962–65 as comparable periods noted for their "fairly well-coordinated relations between agriculture, light industry, and heavy industry" (Liu and Zhao, p. 10).

[2] For Chinese statements on the existence of the agricultural bottleneck, see for example, "Second Shanghai Talk on Mao's Ten Major Relationships" (FBIS).

performance has been outstanding, far better than can be achieved in a market economy context.

The Role of Agriculture

The problems inherent in centralized command systems are magnified in agriculture. The vast number of heterogeneous production units, the spatial dimension, the location-specific nature of the parameters affecting planning and management decisions, and the unpredictable intrusion of special "outside" factors such as weather (with its locality- and crop-specific impact), all tend to go against the grain of centralized direction. A measure of decentralization was accordingly granted when collective ownership by members, as opposed to socialist ownership by all people (as in the case of state enterprises), was instituted in agriculture, coupled with a small, private-sector appendage. But the arrangement created problems of its own. The resulting loss in resource mobility and allocative efficiency and in distributive equity also tends to be cumulative in effect. Moreover, a collective farm is not so much a producers' cooperative to capture scale economies for the benefit of its members as it is an arm of the state whose interest is extractive. There is a sizeable and still growing literature on the economics of the Soviet-style collectives, beginning with Ward through Domar, Oi, Clayton, and recently Batra and Bonin.[3] The weight of the opinion seems to say that collective farms need not be inefficient or provide poor work incentive for peasant households, with recent extensions to decision-making under uncertainty and for innovations. The main drawback with these studies, highly regarded in their own right, is that they take resource fixity as given (rather than as a cost of the policy), ignore location-specificity of farming and lack of scarcity prices in the Soviet-Chinese context, and conveniently assume away the interaction dynamics, between the peasant and the state acting through its agents, within the framework of the bureaucratic and command imperatives. It is a little like saying that the U.S. economy need not be short of the perfect competition ideal; only if government were to bring about corrections through a system of taxes, subsidies, and shadow-price signals. We do not really know how to do all this, of course, any more than the Soviets or the Chinese.

In China, management of agriculture from the center would seem to be especially difficult for the elemental fact that scarcity is a more intractable reality. The residual claimancy status of the peasant in the Soviet Union is at least not all bad. If the peasant has poor work incentive, not knowing what is going to be the worth of the work points he is accumulating, he can be in from time to time for pleasant surprises as when an investment, or innovation, or good team effort paid off. In China, with agriculture acting as the binding constraint on industrialization, the imperatives of the development strategy require extractions approximating the maximum possible. This means a consumption standard close to the basic subsistence and invariant over time. That this was the case during 1952–57 is clear from the official statistics showing agriculture's annual own consumption per capita hovering around 92 yuan in the entire plan period (Tang 1968, p. 474).

Since that time, it is a common supposition among China scholars that, in line with its announced policy, Peking has on several occasions taken measures to improve agriculture's terms of trade (including lowering the agricultural tax from about 12% to 5% of gross output), resulting in a narrowing of the rural-urban income gap that widened in the 1950s (e.g., Schran). However, a possibility arises that the measures taken may not have accomplished the stated purpose if the sector suffered productivity declines. To this question we turn our attention in the following section.

Falling TFPI Trend

Gross farm output (*GVAO*) more than doubled (table 1) during the twenty-seven-year period under review, reaching 205% in 1978 (1952 = 100%), a creditable record with an average compound growth rate of 2.9%. In 1952 prices, our estimated 1978 *GVAO* amounted to 82.4 billion yuan. This is to be compared with 145.9 billion yuan in 1978 prices recently released by the State Statistical Bureau (p. 28). A reconciliation is possible, yielding an implicit price deflator for 1978 of 177% (1952 = 100%) which fits right in with the known Chinese source data fragments on farm purchase price index of about 165% in the mid-1970s (Stone;

[3] For these and other citations, see the two more recent articles by Batra and Bonin, as referenced.

Schran, p. 375). The aggregate input index rose even more rapidly, reaching 242% in 1978. Accordingly, the total factor productivity index (*TFPI*) fell to 85% in 1978. A similar picture obtains in terms of the primary factor productivity index, calculated as a ratio of the value-added index to the primary input index (based on labor, land, and capital while excluding current inputs). Consistent with these productivity trends, value added per worker (in constant 1952 prices), too, declined.

We now return to the question whether terms of trade adjustments since the first plan period have resulted in income improvement for the peasant household. One of the side benefits of a detailed growth-accounting study is that it is relatively simple to calculate, from the basic input-output series, value added in constant prices and to see how the value-added series is altered when changes in relative prices are introduced. Value added by agriculture per worker in constant 1952 prices fell from 280 yuan in 1958 to 194 yuan in 1978. Given the 3:1 ratio (in male prime-age equivalent) between population and worker counts in agriculture, our 1958 estimate of 280 yuan per worker is in close agreement with the official per capita consumption (or retention) of 92 yuan cited earlier. Although the two figures are not strictly comparable, similarity in magnitude is reassuring. The decline in the sector's contribution to the national economy per person engaged is noteworthy and points up the crucial role played by modern nonfarm-supplied inputs in sustaining an output growth characterized earlier as creditable. Adjusting for agricultural tax and a price (received) level change from 125% in 1958 to 177% in 1978, we come up with current price estimates of value added per worker of 312 yuan for 1958 and 406 yuan for 1978.[4] Under stable consumer prices facing peasants, these estimates yield a rise in real household income of some 30%, or an average annual rise of 1.3%. This happens to coincide with our earlier estimate (Tang 1979, p. 55) of 1.33% as annual increase in countrywide personal income per capita, as inferred from the estimated macrodata for 1952–77. Both figures seem to stand in harmony (as argued in the same earlier study) with the recent official releases on Chinese per capita income (taken by us to be personal income) which Vice-Premier Chen Muhua placed at US$139 for 1976. The adjustments made to the value added per worker estimates are not complete. There has been some drop in nonfarm input prices. Offsetting this omission are (*a*) failure to deduct depreciation of farm capital, (*b*) failure to take account of collective deductions (for reserves mainly) before distribution to households, and (*c*) rise in consumer prices "paid" by farm households stemming from imputation of value of home consumption by state purchase prices. In sum, it would appear judicious to conclude that, because of falling farm productivity, Peking's terms of trade adjustments on behalf of agriculture probably have accomplished no more than to keep peasant incomes and welfare from slipping further behind relative to urban standards since the first plan period.

The falling *TFPI*—itself a phenomenon unique among the East Asian agricultures—is best understood against this backdrop of virtually stationary peasant household incomes. For, with proper incentive for workers and their collective leaders, it is difficult to see how the massive injection of modern inputs begun since the early 1960s could have failed to raise productivity. It is equally difficult to see this happening outside the larger context of Chinese development strategy and the adjunct command set-up under conditions of severe scarcity. The preceding sections were offered in that spirit. Before concluding this section, we note that the choice of factor income share weights (for the *TFPI*) is fully explained in our larger study and that our results are only moderately sensitive to alternative systems of weights. None of our principal conclusions are overturned by using any of the weights from East Asian agricultures of any time period.

Weather Disturbance and Empirical Evidence

A decade ago Skinner and Winckler advanced a cyclical theory concerning the compliance cycles in rural Communist China. Using Etzioni's frame of reference, Peking's power relations with the peasant may be said to alternate between the normative, the coercive, and the remunerative in approaches. Sharing the view

---

[4] For 1958: [69.65 bil. *GVAO* 1958 yuan (= 55.68 bil. *GVAO* 1952 yuan × 1.25) × 0.88 (= 1 − tax rate) − Costs (= 55.68 − 49.91 bil. 1952 yuan of value added) × 1.01] + 178 mil. workers = 312 yuan per worker. Cost inflator of 1.01, from Schran (p. 375).

For 1978: [145.8 bil. 1978 yuan (= 82.37 bil. 1952 yuan × 1.77) × 0.95 (= 1 − tax rate) − Costs (= 82.37 − 50.98 bil. 1952 yuan of value added) × 1.0] + 263 mil. workers = 406 yuan per worker.

about the importance of the rural sector, the late Alexander Eckstein argued plausibly for the existence of policy cycles in China related to harvest conditions (pp. 311–22, 332–38). And Oksenberg spoke more generally about the close relationship between Chinese politics and the "agricultural cycle" as an explanation of political changes in the PRC (pp. 107–8). Though differing in emphasis and theoretical underpinnings, the cyclical notions of all these writers are complementary. They give rise to economic policy periodicity alternating between radicalism and pragmatism and impinging on organizational and incentive correlates in agriculture.

It is widely thought that such policy gyrations must have left their impact on agricultural performance. To our knowledge, however, there has been no serious attempt to quantify the relationship. The key problem, as pointed out by Eckstein (p. 321), has to do with the difficulty in determining the extent to which the quality of any one harvest is affected by weather, on the one hand, and by policy, on the other. The sticking point has been weather. There is the usual dearth of Chinese data, although with respect to weather we are relatively well off, thanks to the U.S. intercept program. The real problem lies in our ignorance of crop-specific, location-specific weather and yield relationships in agriculture. And as it impinges on the farmer, weather is a complex multidimensional phenomenon that defies quantification that is meaningful and operational. Thus, there is no national agricultural weather index for any country, the U.S. included. In what follows we shall attempt a crude separation of the influences of weather and policy cycles.

In terms of basic methodology, we take agricultural output in any given year to be determined by (*a*) the amounts of inputs (suitably aggregated) utilized, (*b*) the technology employed whose level bears on input productivity and whose change over time is represented by a secular productivity trend, (*c*) the economic milieu whose critical dimensions, organization and the play of material incentive, oscillate with the policy cycle, and (*d*) weather, treated as a random phenomenon. The conceptualization enables us to employ standard time-series decomposition techniques to separate out influences of weather and policy cycles. As before, we identify performance with productivity instead of output, a move that allows abstraction from changes in inputs.

In figure 2 we present a categorical weather index for each of the years classifying them as "good," "average," or "poor" weather years

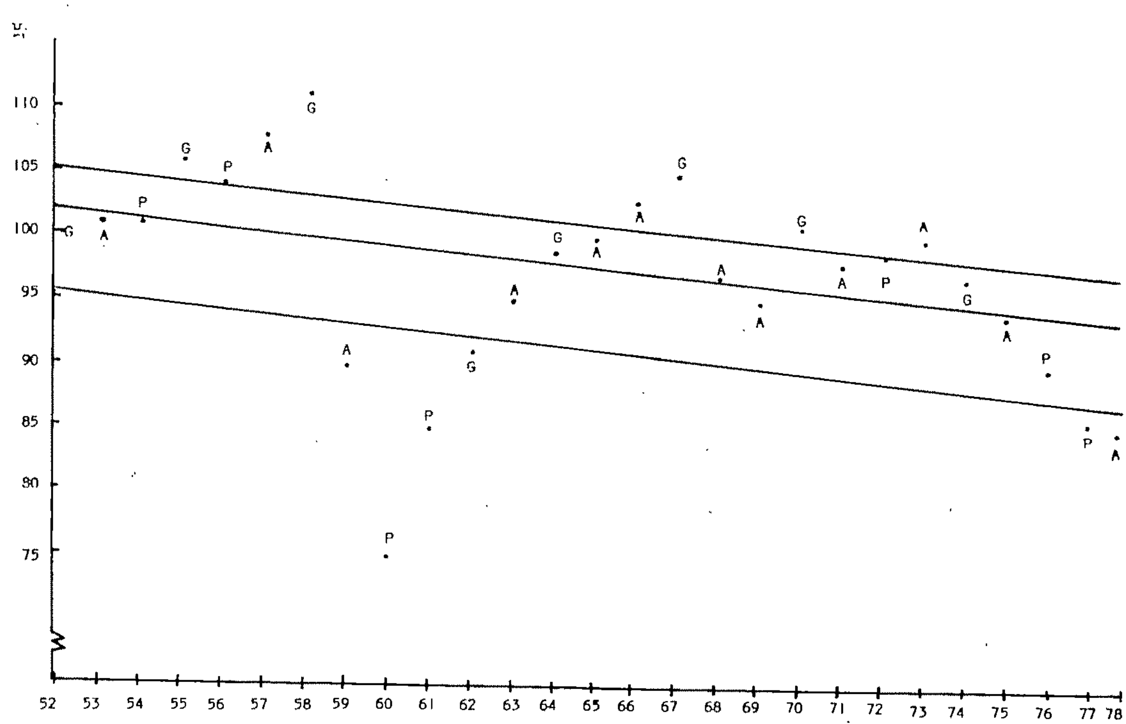


Figure 2. Weather-specific trend lines in *TFPI* ($Y_c = 95.77 + 6.29D_1 + 9.33D_2 - 0.32X$)

for the crops. There were eight good years, twelve average years, and seven poor years during 1952–78. First, separate trend lines were fitted to the three classes of observations without restrictions to see whether the null hypothesis of common slopes is tenable. All three slopes turn out to be in the -0.3 to -0.4 range with insignificant t-statistics. Weather dummies are used next. They enter as intercept dummies with the regression yielding an R-square of .32 and t-statistics on all the coefficients significant at conventional levels. The intercepts for the poor, average, and good years are, respectively, 95.8, 102.0, and 105.1 and the common slope $-.317$. It will be remembered that *TFPI* is the time series with the reference of 100% in 1952, which is also the origin for the trend equation. The empirical evidence on the behavior of the three weather-specific trend lines is of considerable interest because whether or not the lines converge over time constitutes a basis for testing the validity of Chinese claims of having successfully "weather-proofed" their agriculture.

To wring additional information from the data, we applied the Cochrane-Orcutt successive differencing iteration technique in fitting curves to the observations. The procedure is designed to remove serial correlation from the error term iteratively until marginal gain becomes too small to justify further computing. Weather intercept-dummies were used as before. What the procedure amounts to is to fit curves that swing up and down with the (weather-specific) data. With each successive iteration, the residuals come closer to being nonautocorrelated. If our time-series model is $Y = T + C + W$, then the fitted values may be said to represent weather-specific $T + C$ curves. Deviations about these fitted curves may be examined for indications of imbalance between the early and late years as may be brought about by the common-slope restriction. If in effect there was convergence but the fitted lines are required to have common slope, for the poor-weather line, negative deviations would dominate in the early years and positive deviations in the late years. The opposite holds for the good-weather line. No such imbalance can be detected. In sum, the available evidence seems to support the inference that the data do not reject the hypothesis that the weather-specific trends in *TFPI* are parallel. This is actually a strong test because the more plausible model, $Y = T \times C \times W$, would produce arithmetic convergence in the case of downward trends, even if weather's (proportional) effect remained constant. We further infer, therefore, that the weight of the evidence appears strong that the Chinese have not in fact been able to control the influence of weather on agriculture. Accepting the parallel weather-specific trends, it is clear that weather as such has had rather modest influence on agricultural performance in China (unlike Russia and smaller countries such as Japan), as shown by an average difference of only six percentage points between poor and average years and a mere three percentage points between good and average years.

This is at great variance with our expectations. The collective-socialist organization of the countryside, the vast water-control projects, and the concurrent modernization embodying genetic, biological, chemical, and mechanical elements—all are ingredients for making man and his agriculture more resistant to the vagaries of nature. During the Great Leap Forward, excessive zeal and haste did produce manmade errors in infrastructure that compounded the effects of adverse weather in 1960–61. But these problems have long been corrected. Perhaps three speculative offsetting factors are worth stating: (*a*) increased intensity with which land is used reducing the latitude between harvesting and planting needed to cope with weather uncertainty; (*b*) shifts in cropping patterns dictated by Peking's push for local and regional self-reliance and which proved to be incongenial to the natural environment; and (*c*) the command system tends to work less well when farming becomes more sophisticated, requiring a more intricate supply system that involves many producers outside agriculture and demands a high degree of coordination.

Policy Cycle in Agriculture

By taking deviations from the weather-specific linear trend lines, we eliminate trend and the average influence of weather by category. What the procedure leaves are agricultural cycles and a residual irregular component which may be attributed in part to discrepancies between the actual weather conditions of a given year and the average conditions of the weather category to which the year belongs. The latter irregular or random component is "eliminated" by applying ordinary moving averages to the deviations. Figure 3 shows the

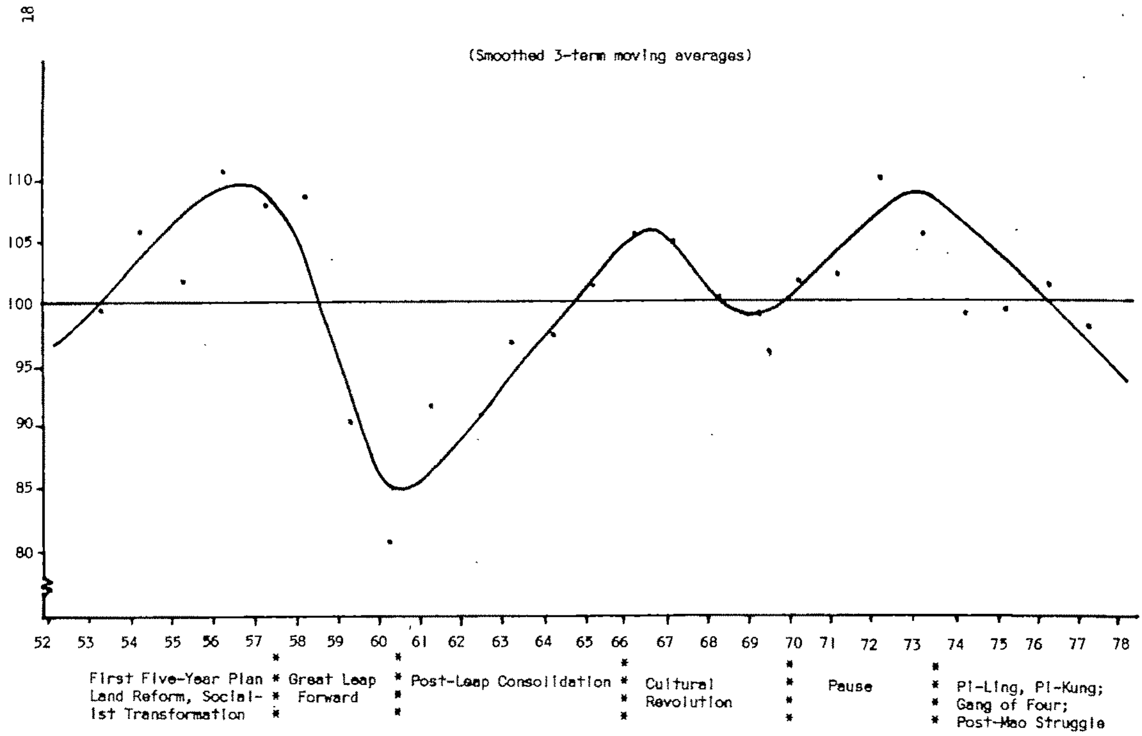

Figure 3. The agricultural cycles in *TFPI*

smoothed path drawn freehand through the (three-term) moving averages. Deviations can be arithmetic or relative, depending on whether one employs an additive or multiplicative time-series model. It makes little difference which form is adopted. In figure 3 the relatives are shown as is consistent with common practice.

An alternative method is to make use of the fitted weather-specific, trend-cycle term from the Cochrane-Orcutt iteration and to divide the term by the weather-specific linear trends. The resulting ratios trace out cyclical configurations similar to what was obtained earlier. Because the first procedure is more straightforward, the results presented here are based on it. These results in figure 3 clearly show that agricultural (*TFPI*) productivity cycles coincide precisely with the known policy or political cycles in China. Productivity rose during the Socialist transformation and First Five-Year Plan period, aided in part by completion of recovery back to prewar peaks and by the taking-up of the then existing slacks in resource use in the form of, for example, fragmented land holdings. Buck once thought that such slacks represented perhaps a potential increment of 25% in output (p. 203). Starting at about 100% in 1952–53, the upswing peaked at about 108% in 1957–58. The downswing brought about by the Great Leap Forward reached the trough in 1960 at around 85%. Recovery followed during the readjustment or consolidation period. Completion of post-Leap recovery was accomplished around 1964; the upswing beyond that point was short-lived, however, peaking at about 106% in 1966 as the cultural revolution began to gather momentum. The drop in agricultural performance turned out to be surprisingly mild as the celebrated radical movement ran its course, bottoming out at just under 100% in 1969. The pause that followed brought agricultural productivity (*TFPI*) back up to about 108% in 1972, only to have the upswing aborted the following year, which saw the beginning of a radical revival launched under the guise or symbolism of an anti-Lin, anti-Kung campaign. As the ailing top leaders loosened their grip on the affairs of the state and the radicals, now known as the "Gang of Four," consolidated their power, agricultural performance continued to suffer. By 1975–76, *TFPI* had dropped back down to 100% and continued to fall as Mao's death and the succession struggle that followed it further weakened order and disrupted economic activities. The slide appeared to continue well through 1978

(when the productivity index reached an estimated low of 85%, with the cyclical relative, however, standing at about 94%) although grain and total agricultural production recovered sharply from the stagnation of 1976–77, thanks to improved weather and massive increases in inputs (especially chemical fertilizers).

Conclusions

The quantitative cyclical record, crude as it is, suggests that, historically, Chinese peasants have responded in a rather predictable and speedy manner to Peking's policy gyrations which impinge on them economically. The close coincidence between agricultural cycles and policy cycles also points up a basic policy dilemma, a dilemma more intractable than in Russia because of China's elemental reality of scarcity. In Eckstein's frames of reference, the clash between the household and the planner, the interplay and clash between ideology and scarcity, the alternations (in Skinner's words) between normative, coercive, and remunerative policy instruments—all are much more immediate and relentless in the PRC. These realities, stemming from the country's unfavorable initial conditions, are also, in our view, at the root of the Chinese secular decline in agricultural productivity, and serve to magnify the problems inherent in the development design and the related command economic system.

It is noteworthy, however, that observed agricultural cycles have become significantly more damped since the Great Leap. Although the cultural revolution was much more far reaching and of greater import politically, its economic impact on agriculture turned out to be almost negligible as compared with the shocks created by the Great Leap. Strenuous efforts were indeed made to keep the cultural revolution from spilling into the economy. Eckstein saw in this encouraging signs of "learning effects" at work (p. 320). Deng, the pragmatist, presumably would take such lessons even closer to heart as he experiments with bold programs never before attempted.

Weather does not seem to loom as large as many have thought as a factor with respect to total output, even less in relation to total factor productivity. This view is consistent with the longer historical record, as well. China is a large and climatically diverse country. Famines tend to be localized and become disasters that attract the attention of chroniclers, for lack of transport and effective central government. It is something of a paradox that, the government's Herculean effort to modify and control "nature" notwithstanding, weather appears to matter as much as ever, in terms of its measured impact on agricultural productivity. The "explanations" that we offer are speculative; more definitive answers await further research.

New Directions in China's Agricultural Imports

Frederic M. Surls

Agricultural imports of the People's Republic of China rose sharply between 1977 and 1979. Grain imports increased to record levels, coarse grains appear to be emerging as a regular import item, China's traditional net export surplus of soybeans vanished, and imports of vegetable oils were substantial. Sugar imports were also well above historical averages and cotton imports reached a record high. This expansion of agricultural imports has been but a small part of a major increase in PRC foreign trade, an increase which has raised total trade in nominal terms by nearly 60% between 1976 and 1978, has seen a large program of complete plant and technology purchases, and has programmed substantial trade deficits for coming years, deficits that will be covered by a sizeable accumulation of foreign debt.

The long-run implications for agricultural imports of developments in the past two years are by no means certain. On the one hand, demand developments in China suggest growing pressures to further increase agricultural imports. On the other hand, limitations on China's ability to export, growing debt repayment pressures during the eighties, and China's new seriousness about acceleration of the growth of agricultural production suggest that the Chinese leadership does not desire substantial further increases in agricultural imports.

This paper identifies and examines some of the major factors that will shape China's agricultural imports during the remainder of the current ten-year plan (1976–85). China's growing imports of textile fibers will not be treated, because they involve, at least in part, a separate set of explanatory variables. The factors discussed below include the aggregate supply-demand balance for key agricultural commodities, the role of state procurements, and foreign trade policies and export growth rates. Each of these has a major bearing on future trade and each is shifting in important but unquantifiable ways.

The discussion includes a qualitative evaluation of the future impact of each of these factors on trade and of the future direction of change of trade in key commodities, particularly grains and oilseeds. This evaluation is based on preliminary results of projection work now in progress and is presented largely for purposes of illustration. The key feature of forecasts of China's agricultural trade is uncertainty. Basic data are lacking and our understanding of both economic structure and past and current economic policies is so poor that the range of possible outcomes is wide.

China's Agricultural Imports

During the past two decades, the PRC was a major purchaser of a limited range of agricultural commodities—grains (particularly wheat), cotton, rubber, and sugar. Overall, agricultural commodities have accounted for between 20% and 40% of all PRC imports during this period. China's imports of food began on a major scale in 1961, the result of the sharp decline in agricultural production following the Great Leap Forward. Major food imports during the sixties were limited to wheat and sugar.

During the seventies, particularly from late 1972 onward, both the scope and annual variability of Chinese agricultural imports increased. Grain imports reached record levels in 1973 and 1974 and the first significant purchases of soybeans and soybean oil came in 1973. Imports of these products fell sharply in 1975 and 1976 as China reduced its overall import levels because of improved production, a substantial trade deficit, and domestic political turmoil. Imports again rose during 1977.

Frederic M. Surls is an agricultural economist in the International Economics Division, Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture.

The author appreciates comments by Charles Y. Liu on an earlier draft of this paper.

Grain imports reached record levels in both 1978 and 1979, soybean imports resumed, and substantial amounts of soybean oil were imported in each of the three years from 1977 to 1979. At least some of the coarse grains imported in 1978 and 1979 were intended for feed use, a potentially important new development in China's grain import program.

The policies behind these purchases have never been elaborated by the Chinese. The beginning of the program in 1961 was clearly the result of dire necessity; at some point afterward, the leadership decided to continue to use imports to supplement state procurements of key commodities from rural areas rather than to increase pressures on the rural sector during years of poor production. This policy was limited in scope, however—restricted at first primarily to grains and, after the first several years, never carried to the point that it eliminated China's net surplus in agricultural trade. This surplus has financed an important share of China's nonagricultural imports.

It appears that the import surge from 1972 to 1974 resulted in part from a liberalization of agricultural import policy—one of the steps taken at that time to reemphasize economic development and modernization and to increase the role of foreign trade. Those steps were temporarily disrupted by the economic and political shocks of 1975 and 1976. But the increase in agricultural imports since then appears to be rooted in policy decisions initially made and tentatively implemented in 1972.

It should be emphasized that the expansion of food imports to date is minor compared with changes in the rest of China's foreign trade. The country has continued to be a net agricultural exporter, the range of imported items remains narrow, and, unlike other imports, there has been no change in China's methods of financing agricultural purchases. These continue to be on a cash basis, with the exception of 12- and 18-month credits for purchases of grain from Australia and Canada, a practice in use since the sixties.

Problems of Explaining and Forecasting Agricultural Trade

It is one thing to describe and generally discuss China's agricultural imports. Attempting to explain past trade behavior and to predict future trade levels is quite another matter. Neither trend analyses nor modeling efforts offer a great deal of help in attempting to analyze trade in individual commodities. Presently available production series for individual commodities are largely estimated and subject to large margins of error. In many cases, production series are based on no more than one to two reports from Chinese sources over the past twenty years—e.g., those for coarse grains and oilseeds (USDA, pp. 31–33). The balance of estimates for the series are based on judgment with only the crudest consistency checks available. In other cases, e.g., total grain production, more complete data are available from Chinese reports but considerable question remains about statistical definitions used by the Chinese, as well as about the quality of Chinese data in a period when the statistical system was only partially functioning. New information released in 1978 and 1979 has greatly reduced questions about current levels of production but uncertainty about levels for earlier years and hence about past trends and annual fluctuations remains.

On the utilization side, virtually no data are available for the past two decades. Hence, independent assessment of these trends is subject to an even greater margin of uncertainty. As a result of these problems, estimating future imports, by starting from an analysis of past trends, is subject to wide margins of error. The small size of trade in proportion to domestic production and utilization greatly compounds this problem.

Attempts to model past trade behavior face even greater difficulties. Although a priori models can be specified, problems with the production series and the absence of data on other critical variables, such as incomes, stocks, state procurements, and domestic prices, limit the value of efforts to quantify relationships. Uncertainty about the timing, nature, and extent of past policy changes affecting agricultural trade further complicates modeling efforts.

Even if past relationships could be quantified, they would be of limited value in forecasting future trade. The domestic and foreign economic policy changes since 1977 are enormous and in many respects represent an entirely new direction for the Chinese economy. Consequently, both supply and demand for agricultural products and demand for agricultural imports have shifted to an unknown extent.

Attempts to analyze quantitatively agricultural trade are not hopeless, however. New

data are becoming available, permitting both pegging of current levels and improving historical series. But productive work in this area is, for the most part, several years away. In the meantime, we are left with judgmental analysis based on very limited information.

The Domestic Demand-Supply Balance

Of the factors shaping future Chinese agricultural imports, the most obvious are shifts in the aggregate domestic supply-demand balance for key commodities. Clearly, the major reason behind China's ambitious plans for expanding agricultural production between now and 1985 is a substantial planned expansion of demand. Among the factors potentially affecting demand growth during the period are falling population growth rates, rising real incomes, and new livestock programs.

Population Growth

China's population growth rate should drop over the next six years. Chinese plans have targeted a 0.5% per annum birth rate by 1985, implying a planned average growth rate of 0.8% per annum for the 1978–85 period. Although a drop of the growth rate to this level is unlikely, Western demographers do project substantial reductions. One widely used population series shows growth rates dropping from a 1970–77 average of 2.2% per year to a 1.3% per year average between 1978 and 1985 (CIA, p. 5). Such a reduction significantly eases demands on agriculture. Using this series, for example, the annual growth of grain production required to maintain per capita consumption levels drops from an average of 4.6 million tons per year between 1970 and 1977 to 3.1 million tons annually between 1978 and 1985; the figure will drop to less than 2 million tons annually if Chinese population targets are met. Other developments, however, will more than offset any reduction in demand pressure due to slower population growth.

Income Growth

There was little improvement during the two decades between 1957 and 1977 in either per capita income or per capita consumption of major agricultural products—grains, edible oils, and meat—or cotton textiles. But growth of income over the remainder of the ten-year plan period will be a major source of increasing demand for these products.

Comprehensive income data are not available. But agricultural procurement price increases and larger procurements from the rural sector, together with wage increases in the urban sector, already have expanded purchasing power. The gains in income appear to have been concentrated in the rural sector; per capita rural income from the collective sector increased by nearly 14% in 1978 and a further 12% to 14% increase is planned for 1979 (Foreign Broadcast Information Service: PRC, hereafter cited as FBIS, 2 July 1979, p. L-14 and FBIS, 3 July 1979, p. L-6). The effects of two major wage increases, together with a recent subsidy for basic food items in the urban sector, have been at least partially eroded by price increases in both 1978 and 1979. On balance, however, it is clear that significant increases in real per capita income, perhaps on the order of 4% to 5% per year, have been targeted for the 1978–85 period, with the larger share of these increases planned for the early part of the period.

Increases of this magnitude will accelerate the growth of domestic demand for agricultural products. At China's current level of development, income elasticities for most basic agricultural products are still substantial. In the case of grains, per capita direct consumption can be expected to rise; in particular, a considerable expansion of demand for wheat and rice can be expected. Demand for coarse grains and tubers for direct consumption will grow much more slowly. Large increases in demand also can be expected for oilseed products (such as oils and beancurd), sugar, meat, and fruits. Most of these commodities are already in short supply at current income and price levels, as evidenced by widespread rationing and illegal price increases.

This growth of demand resulting from higher incomes is a major new development in China's aggregate supply-demand balance for agricultural commodities and is clearly a major factor behind new efforts to increase the rate of growth of agricultural production. However, uncertainty about actual income growth rates and relevant elasticities leaves a considerable range for projections of demand growth.

New Livestock Programs

New Chinese plans emphasize diversification of agriculture, in particular, development of livestock production for both domestic consumption and export. The nature and full scope of plans in this area are unclear. Full agreement may not yet have been reached among the Chinese leadership; the feasibility of rapid livestock expansion is still being debated in the Chinese press.

What is known about plans for livestock development involves both grassland improvement for beef cattle and sheep and expansion of hog and poultry operations in traditional agricultural areas. The latter is of particular interest because of its great potential to increase demand for coarse grains and protein meals.

Pork is the dominant meat produced, accounting for as much as 90% of China's very low level of meat production, reportedly about 7.5 kilograms per capita (*Renmin Ribao*—People's Daily—hereafter cited as RmRb, 9 Aug. 1979, p. 6 and FBIS, 31 Aug. 1979, p. L-29). Hogs in China traditionally have been and remain today largely a by-product of other farming and rural household activities. They are fed primarily on household and plant residues and by-products and on forage, with only minimal use of grain, oilmeals, or other feeds. Weight gain is therefore slow and slaughter weights low. China currently slaughters only about 50% of its annual hog inventory, less than one-third of the U.S. rate. Past policies have overemphasized inventory numbers, with the result that the current slaughter rate is about 30% below that of fifteen years ago (RmRb, 15 Nov. 1979, p. 2). As a result, per capita meat consumption has increased little despite rapid growth of hog numbers.

Any attempt to accelerate the growth of production of meat and animal or poultry products will require more intensive feeding of livestock. One version of the 1985 plan called for doubling of meat production by 1985, to be achieved with only a 30% increase in livestock numbers (FBIS, 31 Aug. 1979, p. L-29). This indicates planned sharp increases in slaughter rates and higher slaughter weights, both requiring substantially more feeding of animals. The grain requirements of such a program are large, although current feeding practices may be so inefficient that the response at the margin to increases in feed may be substantial. Even under conservative assumptions, however, the grain requirements of such a program would be enormous—an additional 25 million to 40 million tons of feed annually by 1985.

One important variable in the livestock program will be the nature and location of new hog and poultry facilities. One proposed feature of the livestock program has been stress on production in urban areas, with calls for achieving urban self-sufficiency in meat production. Rapid expansion of hog and poultry production in this sector would require larger facilities and would be particularly feed intensive. Although there are indications that the PRC is reviewing the scale of the livestock expansion program, a considerable growth of both hog and poultry production will be attempted. The likely per capita income growth rates together with a high income elasticity of demand suggest that demand for meat and meat products will expand by perhaps 40% to 50% between 1978 and 1985. Unless livestock production grows substantially, China will have to impose even tighter rationing or substantial price increases over and above the increase in livestock product retail prices of approximately 30% implemented in November 1979. The livestock expansion program will clearly strain domestic supplies of both grains and oilmeals. Just how much will depend on the actual rate of expansion of the livestock sector, the nature of this expansion, and the marginal response of meat production to increased feed use.

Growth of Production

Given accelerated growth of demand, the growth of agricultural production between 1978 and 1985 is critical to import prospects. This paper will not attempt to present a detailed projection of growth rates for agricultural products, and the wide range of uncertainty surrounding production forecasts should be kept in mind. In general, growth of crop production should accelerate as a result of a combination of increased input supplies, improved incentives, lessened central control with a resulting increase in efficiency, and accelerated technological progress. But the overall growth of agriculture is likely to be less than the 4% to 5% annual growth rate planned by the Chinese. Moreover, production of key products, in my judgment, will not keep pace with the growth of demand, thus increasing

pressures either to import more agricultural products or to alter domestic plans.

Specifically, grain production is likely to fall well short of the 1985 plan level of 400 million tons, a 4.4% average annual rate of increase between 1978 and 1985. The growth of wheat production may about match the growth of demand, but the current production-consumption gap is not likely to decline and may in fact increase somewhat. Coarse grains may well be the fastest growing component of grain production, but demand growth resulting from the livestock program is likely to outstrip the growth of production. Rice production appears likely to grow at a somewhat slower rate than either wheat or coarse grains and will not relieve demand pressures on wheat supplies.

Oilseeds are a second critical category. An early version of the Chinese plan implied a planned 9% average annual rate of growth of production of oilseeds between 1978 and 1985 (FBIS, 31 Aug. 1979, p. L-29). This does not include soybeans, which the Chinese include with grain and for which no separate plan target is available. Increases in oilseed production are likely to fall short of this target and China's demand for vegetable oils will continue to exceed its extremely short supply.

Increased demand for oilmeals due to the livestock program is another important part of the growth of Chinese demand for soybeans and other oilseeds. As nearly as can be determined, protein meals now constitute a very small share of feed rations. Although soybean production should increase, mainly through acreage expansion in the Northeast, the growth of production of soybeans and other oilseeds is unlikely to generate the required meal supplies. This shortage may well constitute the major bottleneck for the livestock program.

Strictly on the basis of this assessment of likely supply and demand developments in China between now and 1985, wheat imports probably will not decline, coarse grain imports should increase somewhat, and either soybean or vegetable oil and meal imports may expand substantially. That last development may be the major change in China's agricultural imports during the next six years. For soybean rather than meal and oil imports to increase, China's crushing capacity will require a considerable expansion and modernization, because much of the output of existing facilities is unsuitable for feed use and is used instead for fertilizer.

Growth of State Procurements

Growth of production is a necessary, but not a sufficient, condition for meeting state requirements for grains and other agricultural products. The urban/industrial sector depends in large part on state procurements from the rural sector; imports of grain and other agricultural products are used mainly to supplement such supplies. For most farm products, then, import demand depends more directly on the procurement supply-demand balance than on the aggregate supply-demand balance for the economy.

Demand for agricultural products in the urban/industrial sector will grow substantially between now and 1985, although perhaps at a slower rate than that of the economy as a whole. Natural rates of population growth in major urban centers already are lower than for the country as a whole and further reductions will be more difficult to achieve. At the same time, reduced controls over rural-urban population movement are probable. Therefore the urban population growth rate will likely increase rather than fall. As noted above, growth in real per capita incomes may be below that for the rest of the economy. But per capita demand for preferred food grains will increase. Additionally, the extent and pace of livestock developments in urban and suburban areas will have an important bearing on future grain demand, although probably not in the next several years. But if an urban livestock program is pushed rapidly, urban sector feed grain demand will be substantially higher by 1985.

While demand from the urban sector continues to grow, two additional sources of demand will compete for state procurements. The Chinese leadership has indicated a desire to increase state stocks of grain; that program probably will take on a higher priority in the future. More important, new agricultural policies emphasize increasing regional specialization as a means of raising agricultural productivity and increasing production of livestock and economic crops. If this shift from past emphasis on local self-sufficiency is to work, the state will have to guarantee supplies of essential food items to areas that increase their degree of specialization. This will require a substantial increase in resale of state procurements to the rural sector of the economy.

On balance, then, demand for state supplies of agricultural products can be expected to

increase considerably between now and 1985. In recognition of this, the 1985 plan calls for a 60% increase in state procurements of grain (FBIS, 6 July 1978, p. E-5). This is a 6% average annual growth rate compared to a planned 4.4% increase in grain production and indicates a planned marginal procurement rate of about 35% during the 1978–85 period compared to an average rate which is probably now no higher than 25%. Much of the planned increase in procurements is intended for resale to rural areas. No data are available for procurements of other crops, but comparable high marginal procurement rates are likely planned.

Achieving this increase in procurements will depend on the overall growth of crop production. But it also will depend heavily on the procurement response to higher price incentives and on the success of state plans for development of commodity bases—specific regions which have been targeted for large state investment and which are expected to have substantially above-average marketing rates. The commodity base program is critical to efforts to achieve substantial increases in procurements.

The increase in procurements over the next six years is likely to fall short of plans. Furthermore, since the growth of agricultural production should be below planned levels and the additional supplies which can be generated by the commodity base program over the next few years are open to question, procurements will most likely fail to keep pace with the growth of demand between now and 1985. This will be another factor adding to increased pressure to import agricultural products.

Foreign Trade Plans and Export Growth

China's trade policies and the future growth of export earnings will have an important impact on the future pattern of Chinese agricultural trade. The PRC is now running a trade deficit and has programmed a growing level of foreign debt to finance imports of complete plants, equipment, and technology. At the same time, strenuous efforts are underway to increase exports, which will become increasingly important as China's debt service costs rise during the eighties.

Plans for agricultural trade never have been made public; but public statements have emphasized expanding agricultural exports, indicating a probable intention to continue as a net agricultural exporter. Trade plans well may envision holding agricultural imports at current levels or even reducing them as new production policies take hold. This would permit a rising agricultural trade surplus and continued use of the agricultural sector to finance nonagricultural imports, although the share of agriculture in total trade would decline with more rapid growth of nonagricultural trade. There have been indications of plans not only to increase traditional agricultural exports, including soybeans, but also to expand the level of grain exports, including coarse grains and, for the first time, wheat.

Such plans could be realized if production grows rapidly enough or if the growth of domestic demand is held down. Examination of domestic developments, however, indicates to me pressures to raise agricultural imports and a growing tension between domestic plans and foreign trade intentions. This tension will increase if the growth of Chinese exports lags and the Chinese leadership attempts to hold down debt levels.

There is no way to project how such tensions will be resolved. It is unlikely, however, that the full burden of adjustment will fall on agricultural imports. Although growing domestic excess demand does not directly translate into higher import levels, it does generate both price pressures and increased rationing as well as pressures to curb the growth of domestic incomes, unless demand is allowed to spill over into higher import levels. The willingness and ability of the leadership to adjust consumption levels to available supplies in the event of a shortfall is open to question and the potential costs to the economy of attempting to do this are greater than in the past. Therefore, excess demand pressures seem likely in fact to translate into higher future imports of key agricultural commodities and a resulting reduction in the size of the agricultural trade surplus.

Conclusions

This survey of factors and developments affecting the future of China's agricultural imports should, in addition to presenting one import scenario, suggest several things. First, a complex set of economic and policy variables will be determining future import levels. Demand growth, in particular, will have to be

recognized more explicitly, as will the role and importance of state procurements in determining import levels. Second, the general factors described here may cause somewhat greater variability in annual imports than in the past. This possibility is reinforced by the apparent importance of areas such as the Northeast in plans to increase state procurements of grains and soybeans. These areas likely are subject to greater yield and production fluctuations than is the nation as a whole. Finally, this survey should clearly illustrate the lack of hard information about trade-determining factors and their relative importance and the wide margin of error which should be expected in attempting to forecast Chinese trade. The uncertainty that this generates should be kept clearly in mind when evaluating PRC trade forecasts. This uncertainty is reinforced by recognition of one implicit assumption made throughout the analysis—general stability of economic policies between now and 1985. A severe plan failure or a change of leadership could lead to a sharp reorientation of both domestic and foreign economic and political policies, with a resulting major impact on agricultural trade.

Chinese Agriculture: Development, Production, and Trade: Discussion

Nicholas Lardy

Although a smaller and smaller share of China's gross domestic product originates in the agricultural sector, the pace of agricultural development has and will continue to be a main determinant both of changes in the Chinese standard of living and of China's overall pace of modernization. Because of the role of agriculture in supplying the major wage good and the complex interrelationships between agriculture and the rest of the economy, great efforts have been made in the West to measure the performance of China's agricultural sector. These efforts have ranged from the construction of independent output series for food grains to more complex efforts to measure intertemporal changes in aggregate per capita caloric consumption or in total factor productivity in agriculture. The major weakness of most of these studies is a lack of adequate underlying data of all types and, most particularly in the case of total factor productivity calculations, of sufficiently disaggregated time-series data for both outputs and inputs. Thus, the drive to present empirical findings can be satisfied only by resorting to a large number of quite arbitrary assumptions. Unfortunately, the most crucial of these assumptions all too often are buried in the footnotes to appendix tables. Because the empirical results presented are entirely a function of the assumptions made, the texts of these papers, in my view, should be devoted to establishing the plausibility of the assumptions made and to examining the implications of alternative assumptions. I cannot emphasize too strongly that, given the paucity of basic data in most cases, plausible arguments can be made for alternative sets of assumptions that have profoundly divergent analytical assumptions. My intention below is simply to raise a number of issues with the hope of suggesting that the secular decline in total factor productivity in Chinese agriculture discussed by Tang should be regarded as a hypothesis rather than an established fact (Tang 1980). These questions fall into several categories.

First, there are several important theoretical questions that deserve close examination. The simple take it or leave it proposition offered by the paper with regard to the methodology employed is not acceptable if one proposes, as this paper clearly does, to draw analytical conclusions from the empirical results. Many of the assumptions necessary for the sound application of the basic Cobb-Douglas methodology simply do not appear to be valid in Chinese agriculture. For example, in the absence of a production function estimate of the elasticity coefficients of the inputs, factor shares from other countries must be used. Given the unusually low land to labor ratio imposed by China's basic resource endowment, one might ask whether other countries' factor shares should be used with such equanimity. Given the underlying relative scarcities in China, the necessary assumption of neutral technological change over the past thirty years is also open to question. It is far more likely that technical change has been sharply biased in a labor augmenting/land saving direction. Thus, even if the initial factor shares were a good approximation of the underlying production elasticities, there is a strong presumption that after technical change accelerated in the mid-1960s, there would be systematic gaps between the production elasticities and factor shares. Thus the use of constant factor shares may bias the results.

Second, there are a number of conceptual errors in the construction of the input indexes that are used. Tang, for example, makes the

Nicholas Lardy is an associate professor of economics at Yale University.

usual assumption that the growth of the capital stock is a measure of the growth of capital services, ignoring the distinct probability that capital services have grown at a significantly lower rate because of shortages of repair facilities, implements, and fuels for various types of farm machinery. There also appears to be some double counting—the index of land inputs is adjusted upward to reflect the increment in yield resulting from irrigation, but diesel and electric power irrigation equipment are also counted in the capital stock. Finally, the labor index is constructed on the assumption that the agricultural labor force is a constant share of the rural population, ignoring a sharp upward trend in rural primary and secondary school enrollment, the rapid growth of nonagricultural employment of rural residents in small-scale industry, and the probable deployment of a growing share of the rural labor force to both rural housing construction and to what the Chinese refer to as farmland capital construction. Again, some of the labor would appear to be double counted because it has already been counted implicitly in the growth of irrigated area.

Third, more recent data suggests that there may be significant errors in the estimates of certain physical inputs and perhaps in gross agricultural output as well. The estimated quantities of chemical fertilizer and insecticides for recent years are higher than the more recently released official data. Part of the discrepancy may be due to quality differences but there should be an across-the-board reexamination of the input estimates to compare them with the newly released official data. On the output side the reconciliation of Tang's estimate (in 1952 prices) of the value of agricultural output in 1978 with the more recent official data (in 1970 prices) requires an implicit price deflator for 1970 of 177 (1952 = 100). Although considerably more research is required, some evidence suggests that the actual deflator is somewhat smaller, perhaps in the range of 150–160. If further research verifies this smaller price deflator, more than half the postulated decline in total factor productivity between 1952 and 1978 would be expunged.

The comments above are directed primarily to the issue of changes in factor productivity over the long run between the 1952–57 base and the most recent years. It should be emphasized that the paucity of information between the periods of systematic release of data by the Chinese State Statistical Bureau (1952–58 and 1977–78), makes empirical calculation for the intervening years even more tenuous. It is necessary to use estimating procedures, such as assumed linear growth rates for intervening years, which frequently results in a smoothed pattern of growth of indexes of both inputs and outputs. Consequently, the analysis of short-run fluctuations in factor productivity should be regarded as more tentative than the long-run trends based on a comparison of 1952–57 with 1977–78.

Finally, setting aside all methodological and numerical disputes, how should one interpret the empirical results emerging from the total factor productivity calculations? In a competitive market framework the residual growth of output that cannot be explained by the growth of inputs has sometimes been taken as a measure of technological change. Of course, numerous refinements in interpretation of such results have been advanced over the past twenty years. But neither the standard nor more sophisticated interpretations may be warranted in the case of the Chinese data. Resource allocation in agriculture does not result from the profit-maximizing behavior of peasants operating in competitive markets but rather reflects a highly constrained process. The government has imposed output and sown area targets on Chinese production units with varying degrees of strictness over time, and inputs and outputs are exchanged at nonequilibrium prices fixed by the state. In short, any index of total factor productivity should be regarded as a starting point for analysis. Do changes in the index reflect technological change or changes in agricultural planning techniques and the structure of incentives? Declining factor productivity with invariant planning and incentive structures clearly would have far different implications for the future of Chinese agricultural growth and the welfare of the Chinese population than would productivity declines reflecting irrational but potentially reversible agriculture production planning practices.

There is no doubt that ill-advised agricultural production planning imposed from above in the years prior to 1978 depressed the growth of agricultural output. When predominantly livestock-raising regions are required to plow up their pastures to grow food grains at yields less than one-tenth the national average, and when some highly productive cropping regions are required to engage in triple-cropping when

there are inadequate supplies of water, labor, fertilizer, and other inputs, there is no question that factor productivity falls (Lardy). But this decline tells us much more about the planning and incentive practices of the 1966–76 period than about the long-term trends in technological change in Chinese agriculture. In my judgment the latter is still largely unknown.

Chinese Agriculture Development, Production, and Trade: Discussion

James A. Kilpatrick

Surls gives us a useful analysis of the factors that are likely to lead to increased agricultural imports over the next several years. The crucial question, however, will be policymakers' reactions to the various pressures Surls describes. He alludes to this at the end of his section on "Problems of Explaining Trade," when he mentions "uncertainty about . . . past policy changes" and describes current policy changes as "enormous."

Chinese agricultural imports have been expanding since the Great Leap. Nevertheless, comparatively large increases in agricultural imports still can be made from year to year without too great expense compared to the Chinese import bill as a whole. Food import levels have been determined mainly by decisions taken under the pressure of events; they are not the result of far-sighted planning on the basis of information concerning numerous economic variables. Surls is correct in noting that over time the level of food imports has ratcheted up in several discrete steps, notably in 1961, 1973–74, and again in 1977–78. Therefore, instead of a smooth course with small corrections, the Chinese have followed a less predictable path. This means, as Surls observes, that past relationships among observable phenomena do not necessarily yield reliable forecasts of future behavior. It is probably this problem of specification that makes econometric work on the import question difficult, even more than the data problems Surls treats at greater length.

Development Policy

Dernberger focuses specifically on agricultural modernization policies, calling them a "crucial determinant of China's success" in agriculture. He emphasizes that agriculture has been treated as "the foundation of the economy," in principle, since the early 1960s. This has not meant that planners' revealed policy preferences have consistently supported this view, but the slogan has been there. Dernberger catalogues the basic elements of the post-Mao strategy in agriculture, and concludes that the nontechnical aspects of this strategy will, in the long run, determine its success or failure. In particular, the new policies may reduce the peasants' attachment to socialist values and will tend to further increase rural income inequalities. The greatest problem of the post-Mao agricultural policies, Dernberger says, is that they are "seriously challenging the objectives of Mao's socialist revolution." This assumes that there is a trade-off between efficiency and egalitarianism, which is very likely true in most of China's countryside. It should be noted that this trade-off has, for the most part and in most places, been resolved in favor of efficiency since the early 1960s. The Chinese have simply not been able to afford to create Maoist man on their communes, and they have not tried all that hard to do so. Out of necessity, those planners with actual responsibility for agricultural output have had to focus on technical modernization and efficient production.

Productivity

Tang's paper builds on his previous work on productivity. He finds that productivity has declined, and that it has responded to cycles in centrally determined policy. It has increased during periods when efficiency was stressed; and it has declined when the leadership has more actively pursued the political goals that Dernberger identifies as the Maoist side of the revolution. Despite declining productivity, Tang finds that the Chinese have sustained a creditable rate of growth over time. The rea-

son for this is that they have had to, in order to keep the agricultural constraint from seriously hindering the growth of the economy as a whole. Tang says that agricultural growth is due in large part to "the crucial role played by modern nonfarm-supplied inputs."

These inputs have not raised productivity over the long run, because of the impact of development policies—both the policies themselves and the way they are carried out bureaucratically. The most aggravating factor, perhaps, has been the leadership's preoccupation with what Tang calls "radical experiment." These experiments, designed both to promote egalitarian social goals and to increase production rapidly, have impeded the efforts of the more sober-minded agricultural planners to use conventional inputs efficiently. Tang points out that policy oscillations appear to have become damped over time. The policymakers' freedom of action has been increasingly constrained by the limited number of options available to them to use to increase production, on the one hand, and the need to keep agricultural stagnation from severely reducing economic growth, on the other.

Prospects

The pressure to raise agricultural output is likely to increase for the foreseeable future, for the reasons Surls describes, while the means available to do so will remain limited. These factors, together with the increasing complexity and cost of agricultural programs, should tend to force planners to choose a path of greater efficiency in the use of resources. This, in turn, may well increase the frustration of those who wish to adhere more closely to more egalitarian (or Maoist) policies. The potential for continuing struggle between the two lines that Dernberger describes will create the temptation for policy makers to attempt programs that are motivated by political desires rather than the need to increase productivity to loosen the constraints subsistence agriculture imposes.

One common thread running through all of these papers is the importance in agriculture of policy choices made centrally. The position of China in trade, in incentive policies, or in the efficient use of inputs or other resources, is crucially influenced by a relatively few choices made on the basis of limited information. Unfortunately, China's leaders frequently have seemed impatient with the constraints imposed on them by agriculture, and have elected to pursue large-scale but relatively simple programs in the hope of obtaining quick and dramatic results.

The most prominent current example of the search for panaceas is the mechanization of agriculture. Despite China's relatively high labor/land ratio, mechanization has interested the Chinese for some time and has sparked a good deal of controversy. The Chinese are now among the largest producers and users of tractors in the world. At the end of 1978 they had over half a million conventional tractors (in standard fifteen horsepower units the number would be over twice this large), and were producing tractors at a rate of over 100,000 per year. This is in addition to over a million garden tractors, which are produced at the rate of over 300,000 per year. Foreign visitors to China and, in some cases, the Chinese press, have noted that many of these tractors are not needed—that they are often left to rust or are used for transportation. But tractor production is still increasing, using resources that presumably could be used more efficiently elsewhere.

As the agricultural sector becomes more complex and more dependent on the rest of the economy, this kind of misallocation is increasingly costly. After all is said and done, the success of China's agricultural modernization, and its trade, depends on how much is produced and at what cost. As a practical matter, gains in output must come mainly from such obvious sources as fertilizer, irrigation, and better seeds, because they work, and because the Chinese have not yet exploited them to the fullest extent. (Chemical fertilizer application in 1978, for example, was 89 kilograms per hectare.)

Therefore, input requirements are likely to grow at a rapid rate. For example, production of an additional 100 million tons of grain over current annual levels (a growth rate just under 3% would produce this result in about ten years), would require large increases in inputs that the Chinese apparently have not yet begun to plan for. The last increase of 100 million tons in grain output (attained between about 1965 and 1978) was associated with an increase of over 10 million hectares in irrigated acreage, 7 million tons of chemical fertilizer nutrients and several million tons of organic fertilizer nutrients, and the extension over a

considerable area of high-yielding seed varieties. The next 100 million tons are likely to require similar increases; larger yields require proportionately more water and nutrients than smaller ones. To speak only of fertilizer, an additional 10 million tons or more of chemical fertilizer nutrients are likely to be needed—equal to the production of more than forty of the largest urea plants the Chinese have imported so far. At the moment, there are few indications that the Chinese plan to build new fertilizer plants at the rapid rate needed to sustain the higher levels of output required. The need for investment in fertilizer plants, as well as other inputs, will further constrain planners' choices in the future.

Publications

Books Reviewed

Clawson, Marion. *The Economics of U.S. Nonindustrial Private Forests.* Washington, D.C.: Resources for the Future, Research Paper R-14, 1979, xxiv + 410 pp., $8.95.

The subject of this book is the nonindustrial private forests of the United States. Since only about 1% of them is larger than 500 acres, and since little is said about the larger ones, the book is really concerned with the so-called "small forest owner problem." Part of Clawson's thesis apparently is that there is no such problem.

Clawson defines his audience as "anyone and everyone . . . concerned with these forests." The effects on presentation are unfortunate, because his attempt to make everything understandable to everyone makes the book at least twice as long as necessary. His purpose is "to present as accurate and as informative a description and analysis of the nonindustrial private forests . . . as it is possible to do with the data available." This he largely accomplishes, and this compendium of statistical and descriptive material makes the book worthwhile. An appendix of sixty-one tables provides detailed statistical background.

But Clawson is not content with description, and it is in his analysis that problems arise. He starts with the statement that "it will be necessary to refute or to correct extensive misconceptions, amounting in some cases almost to myths, about these forests," and says he "will show that such ideas are, in the main, exaggerated or wrong." To anyone who has been involved with nonindustrial forest programs and policies for very long, much of this smacks of setting up straw men for the purpose of demolishing them.

Considerable space is devoted to showing that when the nonindustrial forests are compared with those in industrial ownership on a state-by-state basis, they appear quite similar in productivity, growing stock per acre, and proportional annual yield. Clawson has presented this same idea earlier. He is right that one can only determine whether there is a problem by comparing these nonindustrial forests with something, and there is no absolute standard for this purpose. But his disaggregation of the national data to a state basis sweeps some things under the rug.

The comparison includes only states with substantial industrial forest ownership. This excludes Kansas, for example, which makes the industrial/nonindustrial comparison come out closer because 55% of Kansas' forests are on very poor sites compared to 27% in the nation as a whole. But these low-productivity woodlands may seem pretty important to Kansans, whose state is 97% open.

The weakest part of Clawson's analysis is his attempt to use the neoclassical market model to explain the buildup of growing stock during the past three decades. Most forest economists feel that stumpage supply is largely a stock situation. To the extent that these nonindustrial owners respond to price signals, it is in terms of selling what is already grown and standing in their woods. Any response in the form of management practices aimed at future harvests is hard to document. Where the land has alternative uses, these owners do respond to price changes. But this response has been away from forest use and into soybeans, improved pasture, or housing developments. It has continued despite rising timber prices.

The movement of land into forest and the buildup of growing stock in existing forests has been influenced heavily by institutional factors. Tree planting has been a major part of extension and state forestry programs. Subsidy programs have had an impact. Public fire prevention and control have become increasingly effective. The amount of wood cut for fuel fell off drastically after World War II, and the amount used for farm maintenance has declined with the decrease in the number of farms. As Clawson notes, much of the growing stock consisted of inferior species and qualities for which there were no markets. The trees that were left in the woodlots continued to grow and add to the standing volume. The impact of these factors on the growing stock would have been the same regardless of what happened to timber prices. So Clawson's supply models, which show an increase in current annual growth with an increase in stumpage prices ten or twenty years earlier, may be just a nonsense correlation.

A rather short chapter discusses the managerial problems of the small forest owners. The treatment seems adequate for this kind of book, although it makes little reference to the voluminous literature on this subject. The same cannot be said for the last chapter, which deals with public forestry programs. The treatment here is totally inadequate for a book of these pretensions. The Cooperative Forest Management program receives one sentence, and the Cooperative Extension Service is mentioned only once. It would have been much more informative if Clawson had analyzed the successes and failures of these public programs at greater length, and had devoted less of his space to the detailed statistical analyses of earlier chapters.

Book Review Editor's Note:

The following review differs from other articles normally appearing in this section of the *Journal.* It

is based on the government publication *Structure Issues of American Agriculture*. This report is comprised of essays from a large number of agricultural economists in government service. It has been distributed widely in the profession and received much attention because of its policy relevance.

B. F. Stanton's review, with inputs from R. N. Boisvert, K. L. Robinson, and W. G. Tomek, comments on this effort in a more substantial manner than is possible in the space normally allocated to an individual review.

H. H. Stoevener

ESCS Staff. *Structure Issues of American Agriculture*. Washington, D.C.: U.S. Government Printing Office, USDA Agr. Econ. Rep. 438, Nov. 1979, 305 pp.

In 1979, structure emerged again as a key word in the political economy of agriculture. This large paperback, commissioned rather hurriedly by the Secretary of Agriculture, contains a collection of essays written by ESCS staff to foster discussion and debate on farm structure issues. Many of the authors are well-known in the profession. The report has been widely advertised by the Secretary and broadly distributed. Most agricultural economists in the United States have a copy or ready access to one.

Why all the renewed interest in structure? Certainly part of the explanation is political. But the underlying reasons have more substance. There is growing interest and concern about ownership and control of natural resources—especially productive agricultural land and water. This concern extends well beyond the bounds of production agriculture. Tax laws encourage the accumulation of wealth by commercial farmers. Land prices in the 1970s increased faster than the rate of inflation. The divergence in wealth and income between a thirty-cow dairy farm in Wisconsin and a 1,000 acre wheat farm in Kansas is much more obvious now than ten years ago, even though both are one man, family businesses. There is a back-to-the-land movement among a number of young people from middle income families. There is also a continuing concern for the rural poor who often live beyond the reach of public services on unproductive land and with meager housing. Farmers, leaders in the rest of the food industry, government officials, and the general public feel they have a stake in the way agriculture is organized.

The book and the associated discussion about structure already have accomplished a number of things. (*a*) The book has provided a basic core of information around which national discussion of structure issues can be centered. (*b*) It has summarized current thinking and implicit priorities of USDA economists on these policy issues. (*c*) The overall effort has rekindled interest in the agricultural economics profession to seek answers to the many questions related to structure that remain unanswered. (*d*) It has even prodded some land grant administrators into giving some priority to public policy research and extension.

The book itself considers structure issues in six major sections. The space accorded to each says something about both politics and priorities. J. B. Penn, Deputy Administrator for Economics, ESCS, provides the overview. His is a balanced statement emphasizing commercial agriculture and the dynamic forces which continually lead to change. Babb's two analytical statements on causes and consequences of structural change are particularly useful. Brewster provides historical perspective on national concerns with structure over the years and the changing definitions of family farms. The essays on farm production issues predictably center on land, labor, capital, technology, and management. This section also provides a brief review of what we know and do not know about economies of size, barriers to exit and entry, and alternative forms of business organization.

The middle section, entitled "Public Policies," is also directed primarily toward commercial agriculture. General tax policy, land and water use, price and income policy, environmental regulation, energy, and transportation are all considered briefly. Each of these essays points to ways in which current policy has or may affect farm structure. Very little effort was made to differentiate between what can be accomplished directly through agricultural legislation and associated policy instruments, in contrast to working with more complex problems of general legislation where agriculture is a small part of the political picture. Setting limits on government payments to individual farmers is one thing; changing the rules for individual income taxes is quite another.

The last three sections—"Marketing," "Rural America," and the "Experience of Others"—were assigned less than 90 of the 305 pages. These sections recognize that structure issues involve much more than commercial farming. Input supply, manufacturing and food retailing, the role for cooperatives, and market mechanisms for price determination were emphasized in the marketing section. Structure, conduct, and performance have received substantial attention by economists concerned with the sectors from which farmers buy and to whom they sell. Concerns about thin markets, formula trading, and forward selling activities were recognized appropriately. An examination of the bargaining position of farmers when they buy in factor markets and sell in product markets was not given much attention.

The twenty pages accorded "Rural America" must say something about the low priority accorded within USDA and nationally to part-time farming, rural poverty, and the impact of changing structure on rural communities. Currently two-thirds of the units counted as farms in the national statistics and

more than half of the farm population are located on farms that sell less than $20,000 of farm products. Most of the reduction in farm numbers in recent years has come from these smaller units, and almost none from those with at least one full-time person engaged in farming.

Prices approximately doubled between 1966 and 1978. If one reconstructs the size distribution of farms in 1966 using a 1978 base, one can examine recent changes in that size distribution over twelve years more clearly (table 1). The shift to larger farms is evident but much less dramatic than is frequently recognized when changing price levels are not considered explicitly.

Living on the farms selling less than $20,000 of farm products are a diversity of people with a wide range of interests and problems. This is an area where our factual knowledge about employment, incomes, and opportunities is clearly deficient. Many in this category are part-time operators who prefer to live in the country and combine off-farm employment with some farm production. Some are truly disadvantaged, rural poor, living on unproductive farms with few alternatives. The four essays in this section point to some of the problems and issues, but they provide only a small beginning relative to the size and importance of the problems involved and the difficulty of finding workable solutions.

The preceding paragraphs have tried to provide a glimpse of the materials covered in this generally calm and carefully correct collection of papers. The book brings together in summary form a useful overview of our current state of knowledge about structure issues in their many dimensions. Agricultural economics as a profession has been well served by this initiative.

The very breadth and balance attempted in the coverage of issues leaves a certain sense of inadequacy as well. If one really wants to stir up debate, one needs to concentrate on a few high priority topics, offer some proposals and examine the likely consequences. In many respects this is the challenge that was not faced in this book. But it is clearly left open to readers of this *Journal* to pursue.

Substantial study of a limited number of issues in depth could yield important dividends. Consider, for example, three quite different topics, all related to farm size.

(*a*) *Tax policy.* Observation suggests that tax incentives have been one of the strongest forces leading to increased farm size during the last decade. Can we document the impact of investment credit, capital gains treatment, and the cash reporting option on individual farm growth? Because income tax legislation applies to individuals and businesses generally, what workable options are open to reduce inequities, if they exist?

(*b*) *Payments limitations.* Agricultural commodity programs and disaster loans and payments have differential effects on farms by regions and sizes of units. What are the impacts of current legislation on farms of different sizes and how might differential limits on payments be established?

(*c*) *Statistics on farm numbers and incomes.* Classification of farms into more meaningful groups has not been made. The commercial sector is not identified as such. Sources and levels of income for people living on "farms" where small amounts of products are sold are not known with any degree of confidence. Any efforts to meet the needs of these rural people needs a stronger factual base.

Table 1. Number of Farms by Values of Sales (United States, 1966 and 1978 in Constant Dollars)

Gross Farm Sales	1966	1966 (in 1978 Dollars)	1978
	(thousands of farms)		
Under $2,500	1,389	1,389	916
2,500–4,999	457		279
5,000–9,999	476	457	281
10,000–19,999	445	476	296
Subtotal	(2,767)	(2,322)	(1,772)
20,000–39,000	304	445	323
40,000–99,999	143	340[a]	390
100,000–199,999	43	107	124
200,000 and over		43	63
Subtotal	(490)	(935)	(900)
Total	3,257	3,257	2,672
C.P.I. (1967 = 100)	97.2		195.4

Hannesson, Rognvaldur. ***Economics of Fisheries: An Introduction.*** **Oslo, Norway: Universitetsforlaget, 1979, 156 pp., $18.00 (distributed in the United States by Columbia University Press, New York).**

Hannesson's *Economics of Fisheries* joins the small fisheries economics literature that already includes the recent books by Anderson, Bell, and Clark. Clark's book is confined primarily to the development of mathematical models applicable to living resource exploitation, and Bell's is a far larger work with chapters on aquaculture, recreational fishing, and environmental deterioration. Hannesson's new book has most in common with Anderson's. Both concentrate on the application of standard economic models to commercial fishing. The *Economics of Fisheries* consists of a collection and exposition of theoretical models of fisheries economics, spiced with some empirical examples and numerical illustrations. The first chapter introduces the biolog-

ical basis for much of the theory, explaining concepts from the field of population dynamics such as surplus growth, instantaneous mortality rate, fishing effort, and sustainable yield. Chapter 2 develops the notion of bionomic equilibrium, the state in which both biological and economic relationships are in equilibrium. The bionomic equilibrium is compared to the profit-maximizing yield and effort levels, and the "stock externalities" occurring in a free access fishery are shown to cause a misallocation of resources.

In chapters 3 through 6, Hannesson explains the fishery supply curve and factor rents, develops the concepts of welfare economics necessary to demonstrate the inefficiency of free access, explores the efficiency consequences of sole ownership of fish stocks, and briefly considers the use of taxes and other public policies for managing fisheries. The simple economic model used in these chapters relies upon a surplus yield model of the fish stock, a total cost function, and a revenue function. Constant costs and increasing costs of effort, as well as constant and variable price of output, are discussed thoroughly. The discussion relies primarily on graphs and algebra, but occasionally uses more sophisticated mathematics.

The book concludes with three excellent chapters illustrating the bioeconomic theory with (*a*) a quadratic yield curve, (*b*) a Beverton and Holt-type age-structured model, and (*c*) a Ricker recruitment model. Each of these biological models has important applications in the fisheries literature. Hannesson places each in an economic context and provides numerical examples to highlight specific problems. Because they capably demonstrate how economic models can be linked to biological models, these three chapters provide perhaps the most important and useful contributions of the book.

A blemish in the book's generally thorough coverage of theoretical tools is in the treatment of production costs. With free competition and no fishery regulations, one can assume as Hannesson does, that costs are a function solely of fishing effort. But when the free access fishery is limited by an annual quota, an increasing price of fish will attract additional firms. The annual catch and annual fishing effort will be split among more and more firms as the fleet grows. If there are any fixed costs of entry, the cost per effort will increase with fleet size while the level of effort remains constant. Thus, the production costs cannot be treated as a function of effort if the full range of management devices is to be investigated. Leaving the reader to conclude that control over fishing effort permits control over costs of production, Hannesson provides neither an explanation of the over-capitalization found in fisheries under quota management nor a basis for the use of limited access programs. As a result, the brief discussion of taxation, license limitation, and competitive bidding for fishing licenses in chapter 6 provides no clear framework for economic evaluation of the various management methods.

In addition to this weakness in theory development, the book has some weaknesses in construction and coverage which raise possible difficulties for classroom use. First, the level of economic and mathematical ability required is uneven. To follow the discussion of fishing effort (pp. 17–18) and factor rents (pp. 45–48), for instance, the reader should have a knowledge of microeconomics at the intermediate level. But with this background, the reader will find unnecessary much of the introductory lecture on welfare theory in chapter 4. Similarly, the graphical development of the fishery supply curve in chapter 3 probably will try the patience of the reader capable of handling the Hamiltonian function and Pontryagin maximum principle utilized in the previous chapter's discussion of discounting. A second weakness is the author's frequent tendency to interrupt the smooth development of topics by inserting excursions on subjects covered in greater detail elsewhere in the book.

Finally, while the author intentionally has focused on the development of general theory, the discussion of fishery management or fishery economics cannot proceed far without reference to the institutional and organizational context in which management policy is formed. Nor can the student of fisheries afford to ignore, as Hannesson does, the noncommercial uses of fishery resources. Thus the book does not cover the whole of its subject area. Despite the weaknesses and shortcomings noted here, however, the book is well worth acquiring. The concluding three chapters should be especially valuable to students specializing in resource economics.

Howe, Charles W. *Natural Resource Economics: Issues, Analysis and Policy.* New York: John Wiley & Sons, 1979, xxviii + 350 pp., $19.95.

Howe claims to have developed a textbook which "integrates the field of natural resource economics for the first time" (p. vii). The book reflects a significant contribution toward this laudable goal.

Yet, total integration was not completed and perhaps should not be expected in one book designed for a one semester course.

The book rests heavily on macroeconomics with a complement of capital theory. The Malthusian and Ricardian growth models are developed in a precise manner in the first seven (of sixteen) chapters, drawing heavily on the early work by Barnett and Morse, but supplemented with many original insights. The author's major premise that a simple macromodel can be used to isolate the major issues and yield correct answers (p. 62) may be subject to question, however (see Smith and Krutilla).

The first three chapters are devoted to a definition of issues, establishment of a historical perspective, and an empirical survey of natural resource commodities and stocks. Howe is sensitive to the need to clarify terms (e.g., what is a "resource base" as compared to a "resource" and a "reserve"?), reflecting an apparent predilection toward communication with other disciplines.

The reader is first introduced to models showing gross national product (GNP) as a function of natural resource commodities, labor, and (manmade) capital stock in chapter 2. The very important point that natural resource commodities (e.g., water for irrigation) are produced from natural resource *in situ* stocks (e.g., water in a natural source) through the interplay of socioeconomic forces is made early. The relationship between natural resource commodities and *in situ* stocks, and the interconnection of both with the GNP, is then addressed through gradual introduction of growth and technological change conditions in chapters 4 and 5. Howe does a commendable job of isolating the effects of alternative assumptions about scale elasticity in the resource transformation function.

The relation between remaining resource stocks and the costs of producing natural resource commodities is illuminated in chapter 4. This contribution sets the stage to provide some long needed clarity as regards the rent concept. We then learn later in chapter 5 that optimal resource use over time implies that the price of the resource commodity must be equal to the sum of the marginal loss of environmental services, the marginal cost of resource conversion, and the scarcity rent. Howe has been careful to include concern for environmental costs. He also is willing to admit (chapter 5) that a competitive market may fail to allocate natural resources in the socially desired manner over time; however, a felt need to use the market institution is an underlying theme of the entire book.

Chapter 6 is devoted to a review of efforts to measure natural resource scarcity through various empirical indicators. Factors working to reduce the effects of resource scarcity are reviewed in chapter 7. Issues regarding intertemporal resource allocation, including selection of a discount factor, are discussed in chapter 8.

Chapters 9, 10, and 11 review problems peculiar to the energy, mineral, and forestry resources. Statistics are provided on use and availability; models of exploration and exploitation are presented. Chapter 12, on common property problems, provides the absolute minimum in knowledge required to consider the fishery, water, and natural area-ecosystem resources in chapters 13–15. Interestingly, Howe has chosen to equate "adverse interactions" with "externalities" (p. 241), precluding the possibility of a mutually beneficial interdependency being considered an externality (and a problem) as well. Also, if one followed the Howe book religiously through this section, the topics relating to "public goods," liability rules, decreasing cost industries, and much of the literature on the means to reduce the effects of market failure would not be introduced as the subject matter of natural resource economics. However, Howe does refer the reader to "the many good elementary books" on the economics of environmental management (p. 252). Fortunately, if one heeded his advice, most of this literature also would be taught (appropriately) as natural resource economics.

A major shortcoming of the book is the lack of a cogent attempt to define the boundaries of institutional analysis. The book is traditional, in that institutions are exogenous to the system. This may be especially bothersome to those who have recognized that institutions probably are best thought of as endogenous (Kelso). The traditional approach also tends to treat a natural resource as capital in the production process. While Howe makes some progress here, there is still little new insight into how natural systems can be better represented in a production function. More attention to the agricultural economics literature may have helped (e.g., crop response modeling, pest models, etc). Howe concludes (chapter 16) with an excellent summary of the major issues for natural resource policy.

The Howe book is a valuable addition to the recently started flow of textbooks in the area. With the above caveats, it can be used in a first course for graduate students who are well grounded in quantitative methods and intermediate micro and macro theory. Howe also has recommended its use for upper division undergraduates and noneconomics majors. This could be feasible only with sufficient embellishment by the instructor to clarify and illuminate lectures. The book is well written, with both algebraic examples and "intuitive" discussion used freely to illustrate difficult concepts.

Knapp, Joseph P. *Edwin G. Nourse—Economist for the People*. Danville, Ill.: Interstate Publishers, 1979, 544 pp., $11.95.

Not long ago news magazines asked, "Where have the [national] heroes gone?" They puzzled over whether heroes are nonexistent or merely unrecognized and implied regret over lukewarmness toward them.

Biographer Joseph Knapp asks the hero toga for Edwin G. Nourse, a pioneer agricultural economist who died in 1974. Knapp sees Nourse, however, as a hero not just of agricultural economics, but broadly, of the social sciences made relevant to public affairs. Knapp senses a burden of persuasion arising less from doubt than from an unfamiliarity that he sets out to correct.

Agricultural economists remember Nourse as an early cooperative theorist and an original AAEA Fellow. Less known is that as early as 1916, during a three-year tenure at the University of Arkansas, he compiled a text titled simply *Agricultural Economics* (subtitle, *A Selection of Materials in Which Economic Principles are Applied to the Practice of Agriculture*); that he was the first chairman of a separate department of agricultural economics at Iowa State College; that as a young professor at the University of South Dakota in 1910 he suggested that the state's wheat farmers market cooperatively, and later when at Iowa State he headed a seventeen-man study of West Coast farmer cooperatives; and that he pioneered also in giving status and structure to research in agricultural economics as a member of a committee of the Social Science Research Council, newly established in 1925, where he was "chief proponent" for the Council's making grants "to improve the quality of social science research in agriculture" (p. 113).

Likewise, in his lifelong role of being first in the newest, Nourse left Iowa State after the 1922–23 school year to join the new Institute of Economics of what was to become The Brookings Institution, and from that position he established "liaison" with the just-founded (1924) Brookings Graduate School of Economics and Government. While at the Institute, Nourse published the pathbreaking *Legal Status of Agricultural Cooperation*, and helped establish the American Institute of Cooperation. From the vantage point of the Institute and as a confidant of Henry Wallace, M. L. Wilson, Chester Davis, Howard Tolley, and other leaders, Nourse was in the mainstream of the emerging farm policy, beginning with the Farm Board and continuing through the early Agricultural Adjustment Administration. In 1937, he joined with Joseph Davis and John D. Black in publishing the historic *Three Years of the Agricultural Adjustment Administration.*

Although he periodically dipped into agricultural policy, co-authoring the postwar "Turning the Searchlight on Farm Policy" and never losing his interest in agricultural cooperation, Edwin Nourse turned at mid-career almost exclusively to national economic policy. In 1944, was published his *Price Making in a Democracy,* a title that accurately characterizes his institutional orientation. In 1942, he was president of the American Economic Association (he had been American Farm Economic Association president in 1924) and in 1942–45 was chairman of the Social Science Research Council.

Nourse's growing distinction in general economic issues and policy culminated in his being named chairman—first, again—of the Council of Economic Advisors, the presidential advisory agency brought into being by the Employment Act of 1946. His vicissitudes as Council chairman and his later career will not be annotated here.

Worth noting, however, regarding Nourse's entire career is that he was not an agricultural economist who ventured outside his discipline. Instead, he was a scholar schooled in economics, history, political science, and sociology, whose interests extended to agriculture. Urbane and articulate, he did not fit the stereotype of the agricultural economist. Wrote Joseph Spengler, "I was impressed when I saw Dr. Nourse sculpting for he was the first economist so gifted as to my knowledge. I was struck also by how nicely dressed he was, bow-tie and all, for that did not associate with cooperative marketing and agriculture in my then knowledge" (Spengler to Knapp, 18 June 1973, p. 149).

Nourse's interest in cooperatives was consistent with his self-categorization as an institutional economist.

> I stand for the institutional position. . . . I am interested in the institutions which we have set up as a framework of our economy which we have built up out of ideologies and psychological reactions. This is all tinged with a heavy pragmatic tone. . . . (Nourse to Knapp, p. 469)

Aptly revealing of the Nourse mindset was the title of a 1958 article, "Intellectualism on the Economic Front." Edwin Nourse urged leaders of business, labor, and government to be public spirited intellectuals. He was not happy with organized power groups and hoped their leaders would exhibit "economic 'savvy' and powers of discipline of forbearance" (p. 275). On another occasion he was more hopeful, as he saw new economic thinking as keynoted by "recurring emphasis on 'management' and social responsibility" (1958 *Yearbook of the National Council for the Social Studies*, p. 370).

Joseph Knapp's account is strongest in delineating his hero's conflicts and philosophies, weakest in personal narrative. If a biographer is expected to

reflect, self-effacingly, the biographee's talents rather than his own, Knapp succeeds well. His chronicle of the life of Edwin Nourse has the further merit of constituting a commentary on the fledgling discipline—and profession—of agricultural economics.

Knapp's last recounting is of Nourse's "unfinished symphony" (Nourse's prophetic term, for it was not completed), which, says Knapp, promised "rich insights into the applicability of social science to the major problems of our times" (p. 491). Knapp gives the gist of the "symphony" as his Appendix B. Certain it is that our times can use counsel from the kind of social science intellectual that Edwin Nourse was.

Harold F. Breimyer
University of Missouri-Columbia

Socolofsky, Homer E. *Landlord William Scully*. Lawrence: The Regents Press of Kansas, 1979, xiii + 182 pp., $15.00.

In his prefatory remarks the author declares that the "intent of this book is to narrate for the general reader, as carefully and completely as possible, the life of William Scully." If this were all that the author had accomplished, it is doubtful that the book would be of academic interest to agricultural economists. Even though he disclaims any intent to do so, Socolofsky has woven into his account of the life of William Scully sufficient information about the Irish land tenure system and the development of the Scully leases on his U.S. property that serious students of land economics will find this book rewarding as well as entertaining.

The life of William Scully, a scion of the landed gentry in Ireland, from his birth in 1821 to his death in 1906 spans a period of enormous change in the institutions and attitudes that govern man's relationship to land. Scully is portrayed as an active participant in this process of change, at times resisting it with all his power, and at other times incurring the ill will of his contemporaries because he was too early and too impatient with his own innovations.

Through all this Socolofsky manages to present the evidence available as even-handedly as possible. He refrains admirably from filling in with surmises and judgments where evidence is lacking. Neither does he attempt an evaluation of the life of William Scully or to pass personal judgment on him. The evidence is too fragmentary and already too much tainted by value judgments in the accounts drawn from available media sources. Therefore, the reader is free to draw his own conclusions.

Much of what William Scully achieved, whether for good or for evil, was the result of his own strong will and determination. How many of us would, at thirty years of age, leave a comfortable existence and place a fortune (then) of $85,000 at risk in an alien land? On the other hand, should Scully be credited with a peculiar wisdom in selecting what is today some of the most productive and valuable farmland in the entire U.S. midwest? After all, this was almost the only choice available to him in 1852 prior to the technological developments that later permitted this swamp land to be drained and used intensively in grain production.

Scully's dealing with his tenants ran the gamut from that of a harsh, unfeeling rent-collector, to an advocate of progressive farming who made voluntary rent abatements in years of poor crops and low incomes. Tracing, through Socolofsky's account, the prudence, care, conservatism, and foresight, together with a stubborn insistence on his legal rights, reveals how the purposeful behavior of William Scully, combined with the fortuitous events of his time, resulted in his accumulation of an estate in U.S. farmland that aggregated at one time about 225,000 acres.

Those who would gain a useful historical perspective on policy questions being voiced today about alien ownership of U.S. farmland and about concentration of farmland ownership will find this book enlightening. Unfortunately, they will also find it a bit frustrating in that the author did not choose to write a more comprehensive volume that would have included, among other things, a fuller exposition of the English land tenure system that formed the context for Scully's problems with his Irish tenants. And one could wish for a more complete coverage of the American taxing system as it may have and is now impacting on the Scully estate.

It is quite clear that throughout his life William Scully was strongly motivated by his own self-interest and that of his immediate heirs. Whether this pursuit of his own self-interest also served the interests of society, à la Adam Smith, is an open question.

Walinsky, Louis J., ed. *Agrarian Reform as Unfinished Business: The Selected Papers of Wolf Ladejinsky*. New York: Oxford University Press, 1977, xi + 601 pp., $22.00, $10.95 paper.

Wolf Ladejinsky was a brilliant observer of Asian rural life whose articles, reports, and dispatches were colored by an obsessional fear of communism. His early articles were rather workmanlike summaries of agricultural conditions produced without the benefit of firsthand knowledge. Although they lacked the vivacity of his later field studies, they won him a reputation as an expert in land reform.

His postwar studies seemed to come to life, perhaps as a result of his contact with the lives of the Asian peasant. We can readily see why they won Ladejinsky the support of General MacArthur, who had himself earlier come to recognize the political

necessity of land reform. In part inspired by Ladejinsky, McArthur was convinced that enlightened reform could draw support away from the communists.

Fresh from his initial success in Japan, Ladejinsky was sent to Taiwan and to Szechwan, the last remaining nationalist province on the Chinese mainland. Although reform came too late in Szechwan, on Taiwan a newly arrived force which was free from undue pressure from landlords was able to reap political profit through land reform. During a short trip to Kashmir, Ladejinsky was pleased to discover a roughly similar instance in which the Muslim government was able to expropriate the land from mostly Hindu landlords. In the rest of the Asian continent, the will for land reform was lacking.

National elites whose wealth was mostly based upon land holdings were reluctant to see it redistributed or even to lessen their earnings from the land. Ladejinsky called upon the Ford Foundation to use its resources to subtly prod the Indian government in the right direction before it was too late. But to little avail.

It was already too late in Vietnam, his next assignment. The Viet Minh had successfully preempted the issue of land reform. Reading Ladejinsky's reports from as early as 1955, one can see that the war was already lost. Nonetheless, until 1961, Ladejinsky doggedly espoused the cause of his employer, President Diem.

I have the feeling that the Viet Nam period may have been a turning point for Ladejinsky. Previously, he seemed to exhibit an attitude as if through land reform one could keep "the sheep alive and the wolves happy" (p. 259). Faced with the bloody conflict in Viet Nam, he seemed to plead for effective land reform only as a holding action against the Viet Minh.

The Viet Nam experience might have prepared him to expect the worst in India, but it did not. Afterwards, in his employment with the Ford Foundation and the World Bank, he repeated his fears of imminent communist revolution, but without the same conviction. It seemed to him as if poverty in India was more conducive to patience than revolution (pp. 452, 528–29).

I believe that the reason for Ladejinsky's vision of the future can be understood in terms of his attitude toward peasants. He was undoubtedly a superb listener when he met them. He respected their innate abilities, but the movers and shakers of the world were the elites (pp. 197, 395). To Ladejinsky, Viet Minh were astute politicians who could effectively manipulate the people; the Indian left was to be held up for ridicule. Consequently, he was prepared to see India embark on a process of capital accumulation which would disposses workers from the land; but he warned that the utmost caution was required. Accordingly, he attempted to teach the naive Green Revolutionaries not to make a fetish of new technology.

His brilliant field notes on India were an attempt to bring the technocrats and politicians into contact with conditions in the village. This role exposed the fundamental weakness of Ladejinsky's vision of land reform. His verdict of Indian land reform could be extended to Japan and Taiwan as well: ". . . the people in whose behalf the reforms were designed . . . are the *objects* of reforms, but never the *means* of helping formulate and carry them out" (p. 401; italics in original).

To discover what land reform by the people might mean, one must turn from Ladejinsky to other sources. William Hinton's *Fanshen*, the story of a Northern Chinese village's land reform, for example, illustrated what such land reform would mean.

Hinton, William. *Fanshen*. New York: Vintage Press, 1966.

Waterbury, John. *Hydropolitics of the Nile Valley*. Syracuse, N.Y.: Syracuse University Press, 1979, xii + 301 pp., $20.00.

The Nile is the lifeblood of two countries, Egypt and the Sudan. Egypt, with its dense population confined to the irrigated lands along the Nile, and the Sudan, with a small population but vast potential for irrigation development, are locked into total development of the river. Both countries currently rely heavily on the Nile for irrigation and each plans expansion of water use to meet the needs of rising expectations and population growth. This book expertly outlines the plans and problems that must be faced in such development. Egypt, being a downstream user, long has been aware of its insecurity with respect to water supply should the Sudan lay claim to larger quantities of water. Various schemes have been proposed to alter and increase the flow of the Nile, all of which lie within the Sudan. As long as Great Britain controlled the Sudan and maintained a presence in Egypt, planning for projects to increase the flow of the Nile moved fairly smoothly, although funding was short and progress slow.

With the coming of independence from Colonial rule, some of the stability and cooperation between the two countries has slipped away. No longer is Egypt the stronger voice in development of Nile water supplies. Sudan is beginning to assert its claims on the Nile. Nor is this all; other countries at the head waters are beginning to show an interest in the use of the head water of the Nile. Kenya, Uganda, Zaire, and especially Ethiopia are planning projects for irrigation within their own boundaries.

Each of these schemes has important implications for Egypt because any upstream development ultimately must be felt downstream, as this water no longer flows to the Mediterranean. Egypt, with 40 million people and a high birth rate, needs to expand its irrigated base as well as develop industry to employ its people. So its future demands on the river will be great if the welfare of the country is to rise.

John Waterbury has done a masterful job of detailing the problems faced by two emerging national states as they struggle to gain control of and manage a scarce transnational resource with each insisting upon its sovereign rights to utilize the resource as it sees fit.

The book is divided into eight chapters with an introduction and a conclusion. The first chapter lays out the development that has taken place on the river system. Chapter 2 deals with the political and economic realities that face the Sudan and Egypt. Chapter 3 describes the water supply of the river and the struggle of each nation to develop security to its share of the Nile's flow. Chapter 4 delves into the political machination of the leading powers of the world in developing the Nile, leading up to the development of the High Dam at Aswan.

The effects of the High Dam on the Nile River in Egypt is described in chapter 5. The High Dam, that was to provide new prosperity to Egypt and allow it to control its destiny by capturing the Nile, provides a fascinating study. The effects of the High Dam on water use and development in Egypt and the problems and promise created by the dam follow in chapter 6. Sudan's potential for large-scale agricultural development and the threat to Egypt's need to expand use of the waters of the Nile is detailed in chapter 7. Chapter 8 outlines the potential shortage (and conflict) that will exist on the Nile by 1985–90 if both the Sudan and Egypt proceed with plans to develop and use the water.

Egypt has little choice but to expand use of the water because of its population growth. The Sudan promises to be a rich agricultural exporter in an increasingly shortage-stricken world. Oil funds from the oil kingdoms are beginning to move development in the Sudan, so the stage is set for a classic struggle in which each nation has a crucial stake.

Waterbury suggests four measures which could avoid a major crisis in the use and development of the waters of the Nile: (*a*) The Sudan could freeze its irrigated agricultural base at current levels; (*b*) Egypt could put its efforts into industrial development and delegate basic agricultural production to the Sudan. The two countries could trade industrial goods and agricultural products; (*c*) Both countries could make breakthroughs in efficient use of water in agriculture. And, (*d*) all projects on the upper Nile could be completed in fifteen years with no other country making demands on Nile water. But he concludes that it is unlikely that any of the four are remotely probable.

Waterbury stresses the fact that "Economic and Political Benefit/Cost analysis are not separate fields, and it is because of their interdependence that instrumentalities must be devised to link the technocrat to the politician." Egypt's High Aswan Dam is a case in point. The geo-political benefit of having the key to assured water supply within Egypt's borders, was of overriding importance in creating the Dam.

Waterbury points out that economists and others who work in the field of resource management in the contemporary world must be able to incorporate the political aspects as well as the technical when evaluating resource development projects. This book will be valuable to economists and others who must deal with the relationship between political policy and technological resource development and management.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches. On the left margin, number the lines consecutively.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.

ASSA-AAEA Annual Meeting
Denver, Colorado
5-7 September 1980

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

ISSN 0002-9092

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should now be addressed to the new editor, James P. Houck, Department of Agricultural and Applied Economics, University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the new book review editor Ronald A. Schrimper, Department of Economics and Business, North Carolina State University, Raleigh, NC 27607

Behavior and Productivity Implications of Institutional and Project Funding of Research

Maury E. Bredahl, W. Keith Bryant, and Vernon W. Ruttan

A behavioral model of a research scientist is utilized to develop the characteristics of the demand for institutional (IR) and project research (PR) funds. The demand analysis implies a trade-off between the allocative and productive efficiency of IR funding and the research output mix of PR funding. The model is used to evaluate the formula and competitive grant funding of U.S. agricultural research. We conclude that national research policy should be cast in terms of the relative mix of the two systems of support, not in the absolute merits of either system.

Key words: agricultural research, allocative efficiency, demand for research funds, research-funding policy.

In this paper, we analyze the implications of two alternative research-funding schemes. The first, institutional research (IR) support systems, provides funds to support the research program of a particular research institution. Typically, the funds are not targeted to research areas. Rather, the selection of research areas is made by the administrators of the research institution or individual researchers. The second, project research (PR) grant system, provides support through project grants to individual scientists or research teams. The allocation of research effort typically is determined by the granting agency.

Examples of institutional support for research are numerous. IR was the traditional instrument employed to support federal and state mission-oriented research in the fields of defense, agriculture, natural resource exploration, industrial standards, and related areas prior to World War II (Dupree, Stein). The program of federal support for agricultural experiment stations on a formula basis is a prototype of the institutional research system.[1]

In the private sector, the Ford Foundation has provided institutional support for the research program of Resources for the Future since the early 1950s. Institutional grants were also made to Social Science Research Council to enable the Council to operate the Foreign Area Fellowship Program—a program of project grants. The U.S. Agency for International Development (USAID) provides institutional grants in support of the research programs of the international agricultural research centers which are part of the Consultative Group on International Agricultural Research.

The competitive grant program of the National Science Foundation, in which grant requests are received from individual scientists or research teams and evaluated by peer panels, is a prototype of the project research system. Most of the major foundations and a number of federal agencies operate project research grant programs in addition to IR programs. The project research grant mechanism emerged as a major instrument for linking academic research with mission-oriented federal agencies in the late 1940s and early 1950s (Stein).

The authors are, respectively, assistant professor, Department of Agricultural Economics, University of Missouri; professor, Department of Consumer Economics and Housing, Cornell University; and professor, Department of Agricultural and Applied Economics and Department of Economics, University of Minnesota.

The authors have benefited from comments on an earlier draft of this paper by Emerson Babb, Robert Evenson, Walter Fishel, Edward Foster, Don Hadwiger, R. J. Hildreth, Keith Huston, Yoav Kislev, Michael Lea, Willis Peterson, Jean Robinson, Roland Robinson, Theodore W. Schultz, and Burt Sundquist.

[1] Funds allocated to the states under the Hatch Act, except for funds reserved for cooperative regional research efforts, are allocated to the state agricultural experiment stations by a formula based on the number of farms and the size of the rural population in each state. The several sources of federal funds for state agricultural research are identified in the latest annual report of the USDA Cooperative State Research Service. Factors affecting the support for state agricultural experiment stations have been analyzed by Huffman and Miranowski, Peterson (1969), Heady (1961, 1962), and Dalrymple (1962).

Each of the two research management schemes has strengths and weaknesses. The system constraints and the reward systems are very different under IR and PR research management. The next section of this paper presents an analysis of the behavior of individual scientists in an environment characterized by the availability of centralized project grant systems and decentralized institutional grant systems. We then examine the behavior of research administrators under the two research support systems. Finally, we attempt to draw some inferences from the behavior of research scientists and administrators under the two systems for research system efficiency. The analysis presented here provides a theoretical framework for the empirical evaluation of the gains and losses from the two systems of research management.

The Research Scientist

What objectives does the individual research scientist attempt to maximize? And how does the project (PR) and institutional (IR) research grant systems impinge on the behavior of the individual scientist?

The research scientist has been depicted as both hero (Stakman, Bradfield, Mangelsdorf) and villain (Berry). Our perspective is more modest. The typical research scientist is, as a result of inclination and conditioning, prepared to accept a rather high degree of deferred gratification within the professional reward system. In the immediate postdoctoral years, the scientist is usually willing to defer immediate financial reward for an appointment which assures continued professional development—preferably documented by the accumulation of evidence of research productivity in the form of published papers. If professional productivity is accompanied by reasonable advancement in rank and earnings, the initial research orientation is reinforced. If productivity lags or is not accompanied by advancement in salary or rank, there often is a shift in emphasis toward research that is valued by clienteles other than professional colleagues. This shift toward more applied research also may be associated with a transfer to another institution whose program is oriented more toward applied research. During this process the mid-career scientist may also develop certain entrepreneurial skills. These skills may run in the direction of capacity to generate research support from funding agencies and/or to mobilize the interest and the energies of colleagues to focus their efforts around problems of scientific or technical diversification which require a team effort. Development of entrepreneurial skills often comes at the expense of disciplinary capacity and direct involvement in research.

This description is, of course, highly simplified. And our ability to model is inadequate to deal with even this simplified view. However, we are able to identify several key elements of the individual scientist's objective function that appear directly relevant to the scientist's behavior under the institutional and project grant systems. (Since developing the model, our attention has been drawn to a similar model developed by Becker. His models are, however, designed to address different questions.)

The simplified behavior model that we have developed has the following characteristics:

(*a*) Each researcher maximizes some utility function by simultaneously allocating time between teaching, entrepreneurial activities such as seeking research support, actively working on research, and leisure. The use of leisure to represent nonwork related activities is a common methodological device.

(*b*) Research output is determined by the level of research support available to the researcher and the time spent actively working on research. The researcher faces diminishing returns both in the production of research funds and in the production of research.

(*c*) The transaction costs incurred by the individual researcher in obtaining project research support are greater than those incurred in obtaining institutional research support. However, the level of available IR support may be a binding constraint. That is, IR funds may be rationed and become unavailable before the researcher achieves the equilibrium allocation of time which maximizes utility.

(*d*) Income is a positive function of research output and some measure of teaching and/or extension (or public service) output depending on the way in which a particular scientist's appointment is defined.

Our goal is to determine the characteristics of the demand for research funds. Although several factors influence the individual scientist's demand for research funds, only the cost of obtaining grant and formula funds is considered. Factors held constant include the maximum amount of institutional funds available,

the preferences (utility function) of the researcher, the production function of research output, and the rewards from research output (the income production function). Varying the cost of obtaining research funds allows examination of the impact of alternative research management schemes. Only highlights of the model are presented but a detailed description and mathematical exposition is found in Bryant (available from the author upon request).

The results of the model depend critically on the hypothesis that the transactions cost of the PR system is significantly higher than those of the IR system. In other words the marginal productivity of time spent seeking institutional research funds is significantly higher than that seeking project research funds. Most university scientists can quote examples of the colleague who has spent much more time preparing grant requests for the support of summer research than was spent actually carrying out the grant-supported research. It also seems consistent with experience that the greater the degree of centralization of research management, the greater the costs of grant seeking and the costs of the review and allocation process.

The research scientist maximizes utility by allocating his time among active research, grantsmanship, and leisure (all other activities). Thus, the derivation of the demand for research funds (which reflects the allocation of time to grantsmanship) is similar to the derivation of the demand for a consumption good by the utility-maximizing consumer. However, research funds are an input in the production of research output. The derivation of the derived demand for research funds has certain similarities with the derivation of the derived demand for an input by a profit-maximizing firm.

Before deriving the implications of alternative research management programs, the implication of limited IR funds and different production functions for PR and IR funds are developed. The marginal product of time allocated to production of IR funds exceeds that of time allocated to production of PR funds. Logically, any time allocated to producing research funds will be allocated first to IR fund production. Time will be allocated to producing PR funds only upon exhausting available IR funds.

The assumption of greater cost to obtain PR funds coupled with the limitation on IR funds implies the marginal product of time allocated to production of research funds is a step function. The marginal product is illustrated in figure 1. The marginal product curve is derived simply by increasing the amount of time allocated to producing research funds. The conditions for utility maximization are not required to illustrate the characteristics of the marginal product curve.

Initially, any time allocated to producing research funds (T_k) will be used to produce IR funds (T_h). This maps the *ab* portion of the marginal product curve. At *b*, the amount of IR funds available (requiring a time allocation of T_h^{max}) is exhausted. Hence, additional allocations of time can produce only PR funds (T_g). But the marginal product of the first unit of time producing PR funds is less than the last unit producing IR funds. The differential costs result in the discontinuous portion of the curve, labeled *bc*. Allocation of time to producing research funds beyond T_h^{max} produces only PR funds mapping the *cd* portion of the marginal product curve.

To this point, the optimum allocation of time has not been considered. The desired statement of the demand for research funds reflects alternative research management schemes. The cost of obtaining research funds is varied by shifting the marginal product curve illustrated in figure 1. A reduction (increase) in the cost (marginal product) of obtaining research funds shifts the curve upward. To determine the characteristics of the demand for research funds, the marginal products of time producing formula and grant funds are exogenously and proportionately varied.

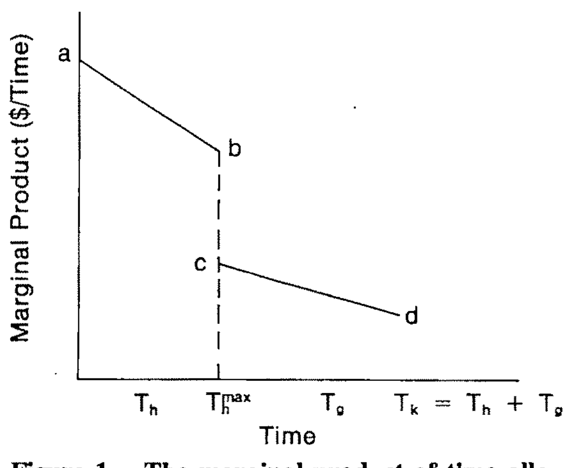

Figure 1. The marginal product of time allocated to obtaining research funds

In the analysis, increases in the marginal productivity of time allocated to producing research funds is synonymous with a reduction in the cost of obtaining research funds. Cost in this context may be thought of as the amount of time in other activities (and the associated income and utility) that must be foregone in order to obtain research funds. That cost reflects the research management system.

Initially, assume the cost (marginal product of time) of research funds is relatively high (low). At equilibrium, relatively little time is allocated to producing research funds (K). Hence, a relatively small amount of research funds will be demanded. Further decreases (increases) in the cost (marginal product) will increase the demand for IR funds until all available IR funds are exhausted (K_h^{max}). This maps the *ab* portion of the demand for research funds illustrated in figure 2.

Further decreases in the cost of research funds will not increase the quantity of research funds demanded. The optimum allocation of time to producing research funds occurs along the discontinuous part of the marginal productivity curve (*bc* in figure 1). Hence, the discontinuous characteristic of the marginal product curve maps the *bc* portion of the demand curve for research funds.

Still further decreases in the cost of research funds induce the allocation of time to producing PR funds (K_g). This maps the *cd* portion of the demand curve for research funds. The effective demand for research funds is *abcd* as illustrated in figure 2. The implications of the

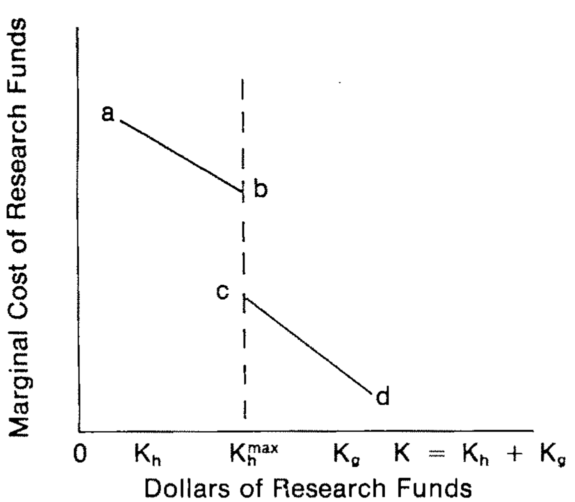

Figure 2. The individual's demand for research funds

step function characteristic of the demand for research funds are now developed.

First, at any institution there will be those scientists with so low a demand for research funds that they are not constrained by the limit on IR funds. These will be individuals who are very productive in nonresearch activities relative to research and those with high marginal products of labor in research relative to the marginal product of research funds. The former will specialize in teaching, extension, and administrative activities, while the latter will be the "pencil and paper" theorists. Both will operate within the *ab* portion of the demand for research funds and will not be affected by K_h^{max}. Of course, the more affluent the institution, the larger K_h^{max} likely will be for any individual. We would expect, therefore, interinstitutional differences in the proportion of faculty operating in the unconstrained *ab* portion of the curve. Depending on the allocating conventions of experiment stations, some fields may be allocated relatively more than others and so the scientists within these fields likewise will be less constrained.

Second, there likely will be a number of individuals at any institution who operate in the *bc* portion of the demand for research funds curve. Such individuals would demand more IR funds were such funds not rationed. But, they demand no competitive funds (K_g) because the marginal cost of K_g (the marginal value of the foregone leisure) is greater than the increment to income the added funds would bring. The number of such researchers who are thus "immobilized" depends, of course, on the length of the discontinuity, *bc*. It will be longer (and thence the frequency of immobilized researchers greater), (*a*) the greater the difference in the marginal costs of IR and PR funds, (*b*) the better substitutes research funds and researcher labor are in research, and (*c*) the better substitutes teaching, extension, administration, and research activities are in yielding income to the individual.

Third, within the range of the discontinuity, *bc*, while the demand for research funds is invariant, the amount of research done is not. Because he is barred from PR funds by their high marginal cost, the researcher may substitute his own labor for research funds and continue to increase research output, subject, of course, to greater diminishing returns than otherwise would exist. The labor intensity of the research, then, will increase as a result of

the limitation on IR funds and the high cost of competitive funds.[2] This labor intensity with respect to the primary researcher's labor also may involve changes in the research output mix: more theoretical work, more use of secondary data, smaller and fewer experiments, smaller and fewer instances of primary data generation as the research becomes more labor-intensive.

Fourth, another impact of the discontinuous demand for research funds is to increase the labor devoted by the scientist to other aspects of his (her) appointment: teaching, extension, administration. Consulting activities also can be expected to increase. Again, this bias toward nonresearch activities will occur to the extent that the individual has a positive demand for income (is not in the backward-bending part of his supply curve of labor), and the marginal wage rates for the nonresearch aspects of his (her) appointment are positive. Therefore, not only does the limit on IR funds and the high cost of competitive funds increase the labor intensity of the research enterprise of those caught in the discontinuity, it also has the effect of increasing the labor intensity of all other aspects of the individual's job.

Fifth, those not caught on the discontinuity and who have high enough demand for income (consumption) compete for PR funds and operate on the *cd* portion of the demand for research funds curve. The research outputs and incomes of such individuals are higher than those who operate on the *ab* and *bc* portions of the demand curve for the research funds. Because the marginal cost of PR funds is much higher than the cost of IR funds, the research funded with IR and PR funds will be more labor-intensive than the research of those operating on the unconstrained, *ab* portion of the curve. Whether the research done on the *cd* portion of the curve is more or less labor-intensive than those caught in the discontinuity depends on the difference in the marginal costs of PR and IR funds: the greater the difference, the more likely the research of those caught in the discontinuity will be more labor-intensive than those demanding PR funds. One way of looking at this is that as the difference between the costs of the two types of funds increases, more of the scientist's time must be devoted to grantsmanship and less to direct research activities if he (she) is to compete for PR funds.

Sixth, it is likely that a reduction in IR funds with the consequent increased stringency with which remaining IR funds would be rationed among researchers (a shift to the left of $K_h^{\max}$ in fig. 1) will increase the difference between the marginal costs of IR and PR funds. As IR funds are increasingly rationed, more individuals will be pushed from the *bc* to the *cd* portion of the demand for funds curve and will compete for PR funds. The increased number of competitors for PR funds will drive down the probability of acceptance of any given proposal and so raise the marginal cost of grantsmanship. A transfer of the reduced IR funds to PR purposes (as the USDA proposed in 1978) will increase either the number of PR projects funded or the level of funding per project and so increase the expected yield per proposal. The net effect of these two changes is unclear. If academics are as risk-averse as recent writings on the economics of academic tenure and retirement suggest, the decline in the probability may well be more important than the increase in PR funds. If so, the marginal cost of PR funds will rise. A possible result of transferring funds from IR to PR purposes, therefore, will be to increase the proportion of researchers immobilized in the *bc* portion of the curve.

Seventh, it is worth noting that given a distribution of grantsmanship skills among scientists, the greater the difference between the marginal costs of IR and PR funds, the greater the likelihood that specialization of function will arise among scientists. The more skilled as grantsmen will specialize in the activity doing little or no actual research.[3] And with the PR funds, they will hire scientists relatively more skilled in research to which they will allocate research funds.

The Research Administrator

An assessment of implications of a project research grant system relative to an institutional research grant system must consider the ef-

[2] In this instance and hereafter when labor intensity is discussed, it is researcher or project director labor that is being referred to. Within the limits of IR and PR funds, other labor (graduate students, postdoctoral fellows, research assistants, secretaries, and the like) may be employed to carry out particular facets of the research.

[3] There is some evidence to the effect that younger scientists are more active in journal publication than older scientists and that the marginal value of a journal article, in terms of income, declines with the scientist's age (Peterson 1973, p. 14).

fects of the two systems on the behavior of the individual scientist. In this section we suggest how the project and institutional research grant systems impinge on the behavior of the research administrators. We shall be particularly concerned with the impact on the behavior of the director of an agricultural experiment station, research center, or laboratory located within a university environment.

Our description of the objective function of the research administrator is largely intuitive. Kaldor (1971, 1978) repeatedly has pointed to the dearth of systematic knowledge about the decision-making processes used by research administrators. Most of the knowledge that we do have is based on casual observation and introspection. Nevertheless it does seem feasible to specify some of the elements that enter into the decisions of research administrators and scientists.

The typical research manager tends to have a view of the world which places a heavy weight on the value of new knowledge and new technology and places a low weight on both the direct and indirect costs of research and of technological change. The administrator visualizes an almost "endless frontier" waiting to be discovered, with limited financial, physical, and professional resources. The administrator's standing, both within his (her) own institution and among outside collegiate and clientele constituencies, is directly related to the ability to assemble or develop a research staff that is recognized for the quality of its work or its value to clientele constituencies. Within public sector institutions, where the salary structure is somewhat bureaucratically determined and has little flexibility at the top, prestige considerations carry greater weight. In the private sector, where the output of the research laboratory is evaluated more directly in terms of the enhancement of the firm's profits, productivity is given more weight.

The net effect of these considerations leads a research director to measure success in terms of the capacity to acquire additional resources and the ability to utilize these resources productively. The measurement of the quality or the value of research output at the individual scientist or research team level is highly subjective, and the management of research enterprises is highly collegial. These factors tend to lead to an emphasis on the quality of the major input, professional personnel, relative to the value of research output. Emphasis on more effective monitoring of research output is greatest in those cases where there is strong clientele pressure. Clientele pressure on research management is reasonably strong in state and federal agricultural research programs because of the close feedback loop between farmers, legislators, and research institutions (Hayami and Ruttan, Guttman).

The above description of the elements that enter into the objective function of the research administrator or manager is not inconsistent with the utility function of the bureau manager that has been suggested in the literature on bureaucratic behavior (Niskanen; Ruttan). In that literature it is assumed that the bureau manager's utility is a function of (*a*) the bureau's output, (*b*) the bureau's discretionary budget. In the case of the agricultural experiment station or the agricultural research institute, we can interpret bureau size in terms of research staff and the output of applied research that is valued by the research institution's clientele. Discretionary budget can be interpreted in terms of funds to support more fundamental (basic or supporting) research and for related professional activities (seminars, symposiums) that serve to enhance the capacity of the research staff or the prestige of the research unit. It represents funds that are not required to meet salaries and other overhead items. This description of the utility function of the research manager involves an even greater simplification of a complex reality than our description of the utility function of the individual research scientist. It does, however, appear to capture important elements of the research manager's motivation.

If incremental growth in research funding is primarily in the form of project rather than institutional research support, as suggested in the introductory section, one effect will be to reduce the discretionary resources available to state experiment station directors. A higher proportion of institutional support funds will have to be devoted to salary and overhead items. Capacity to mobilize resources for problems of significance at the state or regional level will be reduced.

We are now ready to combine our analysis of the effects of the institution research grant (IR) and the project research grant (PR) systems on the behavior of the individual scientist and research administrator, on the efficiency

or the productivity of the research system, and on the strategy alternatives available to research administrators.

Some Research Management and Policy Implications

The goal of a research management system is the production of the socially desired mix of research output at the minimum social cost. Our analysis suggests that the institutional research management system entails lower transactions costs than the project research management system. On the other hand, the project research management system enables the control of the mix of research output at a central (national) level. Advocating one system in preference to the second involves the trade-off between central control and system efficiency.

Research Efficiency

It would be surprising, however, if optimization of the objective functions of research scientists and administrators would lead under most circumstances to system efficiency. System efficiency is a function of the institutional environment, including the structure of incentives and constraints, in which scientists and administrators carry out their professional responsibilities. When we examine the implications for the behavior of scientists and research administrations under the IR and PR systems, some rather clear-cut empirical generalizations concerning system efficiency emerge.

First, the external PR grant system diverts efforts by individual scientists from research to grant seeking and related entrepreneurial activities (Foster 1979a, b). This is why the PR portion (section *cd*) of the individual researcher's demand for funds lies below the IR portion (section *ab*). More directly to the point, in 1978 the U.S. Department of Agriculture (USDA), which administered a competitive grant program of $15 million, received more than 1,100 research proposals involving funding requests for over $200 million (USDA 1978b). Similar ratios have been noted for other grant programs (Leopold). In addition to the time devoted to the preparation of unfunded grant proposals, substantial time also is devoted to peer review and administration.

A major structural feature of the competitive grant system clearly induces excessive allocation of scientific effort to grant-seeking activity. To the individual researcher, the supply of PR funds appears relatively elastic (with respect to effort devoted to grant seeking). Each individual project is small relative to the resources available to the granting agency. In the aggregate, however, the supply of research funds is relatively inelastic in the short run. An increase in the number of projects submissions results in an increase in the share of research resources devoted to grant seeking relative to research and an increase in the bureaucratic resources devoted to grant management. It also may result in smaller average size of individual grants and fragmentation of research effort.

Second, in a system which limits institutional support primarily to personnel support for core scientific staff (such as tenured professors) and capital equipment (such as laboratory space and computing equipment), incremental research costs must be covered by project grants. Over time, a research institute committed to solving a particular scientific and technological problem, adapting soybeans to shorter growing season environments for example, may find its staff responding more to priorities of external funding institutions rather than concentrating its effort on the crop improvement mission. It is not difficult to imagine a situation where a university administration begins to value its agricultural (or space science) research capacity less for the significance of the scientific and technological knowledge it produces than for the overhead generated by research grants or contracts.

This problem appears to be most acute in situations in which institutional research support has been closely linked to, or hidden by, reduced teaching loads. In the 1950s and 1960s many universities used expansion of undergraduate education to support the expansion, almost surreptitiously, of their institutional research support (Keyfitz). This has created two important problems in a period of declining or shifting undergraduate enrollment. Institutional research support by discipline or problem area expanded in response to differential rates of growth in undergraduate enrollment. Likewise during a period of declining or shifting enrollment, institutional support is eroded

for considerations unrelated to scientific opportunity or technological priority. As noted earlier, institutional support for agricultural research has not been as closely coupled to undergraduate enrollment as in many other areas. There are, however, substantial pressures in some states from university administrators and state legislative committees to conform to university-wide standards with respect to student-teacher ratios. In the future, effective allocation of institutional research resources will require the development of budgeting mechanisms that more effectively uncouple the institutional support for teaching and research activities.

Research Mix

One major advantage that is sometimes claimed for a project grant system is its flexibility in redirecting research effort into areas of new scientific interest or technical concern. Research systems that rely primarily on institutional support have been characterized as limited in their capacity to reallocate scientific and financial resources from traditional areas of concern or staff capacity to new areas. The state agricultural experiment stations in the United States have been criticized for devoting excessive attention to problems of increasing food and fiber production and as unresponsive to environmental and human concerns in a period of changing social values (Paarlberg). In the United Kingdom, the national agricultural research institutes were criticized in the Rothschild report for devoting too much attention to basic research and being unresponsive to the needs of the farmer and the food industry (Ulbricht).

A second argument that is sometimes made for a competitive project grant system is that it creates a marketlike environment for both talent and ideas. This argument frequently is coupled with arguments in favor of a peer review system to assure competent scientific judgment and effective quality control in the allocation of research resources (Cole, Rubin, Cole; Bowers; Gustafson).

Both arguments have a great deal of intuitive appeal when used to support the proposition that a centralized project research grant is itself a powerful force for conformity. We have great difficulty, for example, visualizing how a peer panel might have reacted in 1900 to a proposal from a young physicist named Einstein, who had just published his first professional paper, for support of a project which had as an objective the development of a unified theory embracing mechanics, optics, and electrodynamics—and without resort to conventional laboratory technique.

The Management of Research at SAES

The sources of funds available to U.S. state agricultural experiment stations have consisted primarily of federal funds appropriated to the states on a formula basis and of funds appropriated for agricultural research by state legislative bodies (table 1). Although federal "formula" funds are granted to the state on a matching basis, in recent years most states have supported agricultural research at a level that substantially exceeds the federal matching requirements. In addition to federal and state funds, many state agricultural experiment stations also obtain substantial contract and grant support from private industry, private foundations, the U.S. Department of Agriculture, and from other federal and state sources. The contract and grant support from other federal agencies and other sources has tended to increase slightly more rapidly than the traditional sources of funds.

The last decade has been characterized by a growing lack of confidence in research decision-making processes (Berry; Bonnen; Hadwiger; Mayer and Mayer; Meier; Paarlberg). In the United States the agricultural research establishment has been viewed as unresponsive to environmental, distributional, and humanitarian concerns. New clientele groups have attempted to move concerns such as nutrition, rural development, environmental impact, soil conservation, and the problems of hired workers higher on the research agenda.

Partially in response to this criticism, Congress established a federally funded, competitive, research grant program open to all scientists and administered by the Competitive Research Grants Office of the USDA Science and Education Administration.[4] The FY 1978 appropriation act made a total of $15 million available for competitive research grants. The executive budget for FY 1979 proposed that the competitive grants program be increased by an additional $15 million (table 2). This was

[4] A program of special grants that were competitive among state agricultural experiment stations was initiated in 1970. These funds rose from $2.8 million in 1970 to $16.2 million in 1979 (table 1).

offset by a reduction of approximately $11 million in Hatch Act formula funding plus reductions of approximately $1.0 million in McIntire-Stennis Cooperative Forestry Research, $2.0 million in special research grants, and $1.5 million in rural development research (USDA 1978a, c; Strobel). The 1979 appropriations act finally passed by Congress restored the cuts in Hatch Act funds that had been recommended by the administration and continued the competitive research grant program at the $15.0 million level. The executive budget for FY 1980 proposed a continuation of Hatch funding at the FY 1979 level and an increase in the competitive grants program from $15.0 to $30.0 million. The FY 1980 appropriations, however, increased Hatch funding by $9.5 million and the competitive grant program by only $1 million.

Strong support for a program of competitive

project research grants to be administered by the USDA had been made in two reports sponsored by the National Research Council (1973, 1977). The National Research Council recommendations reflected, in part, a judgment that the productivity of agriculture and agriculturally related research could be enhanced by making USDA research support available to scientists in departments and institutions that had not been eligible for support under the formula-funding arrangements.

Administrative officers and scientists at the state agricultural experiment stations also had been generally supportive of the move to expand funds for competitive grants (Babb). Both the National Research Council and the leadership of the state experiment stations, however, had expected that an expansion of funds for competitive research grants would take place in an environment of expanded support for agricultural research. Apparently they did not anticipate the trade-off between the competitive grant and formula funding that emerged in the FY 1978 executive budget proposal.[5]

The argument for expanding support for agricultural research typically has drawn on two sources of support. Agricultural scientists and science administrators have pointed to the technical constraints that must be overcome to meet future food and fiber requirements. They also have argued that technical change leading to lower production costs represents one way of balancing the conflicting claims of farmers for higher incomes and of consumers for restraint in food price increases. Economists have buttressed these arguments with an expanding body of empirical research which has documented the high rates of return to past agricultural research (Boyce and Evenson; Bredahl and Peterson; Arndt and Ruttan). In recent years, they also have worked closely with research administrators to provide *ex ante* rate of return projections.[6] Both the constraint and the rate-of-return approaches suggest substantial underinvestment in agricultural research both in the United States and in most other countries where such studies have been conducted.

Evaluation of Current Research Policy

We have noted that the effect of a system which appears optimal to the individual scientist or to the individual research manager in a world characterized by limited institutional support and substantial project research support alternatives is to (*a*) induce both excessive allocation of professional resources to grant seeking and (*b*) contribute to the disintegration of the capacity to undertake major mission-oriented applied research programs. These two sources of inefficiency can be reduced by utilizing an institutional research strategy as the primary device for the support of mission-oriented applied research and for basic research which directly relates to the needs of an applied research program.

There is substantial evidence to support the claim of efficiency for the institutional support system. High rates of return have been attributed to the state and federal agricultural research systems in the United States, to a number of older research institutions in former colonial countries (such as the Rubber Research Institute of Malaysia), and to the older units of the CGIAR-sponsored international agricultural research system (Evenson; Evenson, Waggoner, Ruttan). It would be extremely difficult to imagine that the long-term research effort required to develop the high-yielding clones which have revolutionized productivity in the Malaysian rubber industry could have been accomplished on the basis of a series of project grants from a colonial research secretariat in London.

The inferences drawn from agricultural research are consistent with the experience of a number of highly productive industrial research programs. Mansfield et al. (p. 157) have documented rates of return to industrial research in the same range as the rates of return to public sector agricultural research. The more productive private research programs typically have been those which have combined long-term sustained support by a firm with a sufficiently broad product line to be

[5] Dr. M. Rupert Cutler, Assistant Secretary for Conservation, Research, and Education, USDA, appeared to be surprised by the results of his own budgeting efforts. In response to committee questioning on this point he responded (p. 91, 92), "That apparent relationship was unintended. By that I mean the relationship between beginning a competitive grant research program open to all agricultural scientists and the level of the Hatch Act budget request." Cutler went on to explain that many of the programs of the USDA (entitlement and regulatory programs) are legislatively determined. Given a budget ceiling, the remaining funds available for agricultural research programs are fixed. Thus the only available method to initiate the competitive grants system was the reduction of other research areas.

[6] For a review of the methodologies for estimating *ex ante* values of return see Fishel, Puterbaugh, and Shumway. For an attempt to develop *ex ante* rate-of-return estimates see Araji, Sim, and Gardner.

able to utilize a substantial share of the product of a major "in-house" research program (Mueller).

Finally, one can point to the productivity of a number of long-term institutional research support activities by the private foundations. The support by the Carnegie Institution for the fundamental studies on inheritance in maize by George H. Schull is a classic example (Sprague). The Rockefeller Foundation support for the research program of the Office of Special Studies in the Mexican Ministry of Agriculture over several decades (from the mid-1940s to the early 1960s) established the basis for the research program of international research centers which are part of the Consultative Group on International Agricultural Research (CGIAR) system. The Ford Foundation institutional support for the research program of Resources for the Future has been a major factor in establishing resource economics as a major field of economic research in the United States.

Qualifications and Conclusions

Long-term institutional research support also can become a source of inefficiency. Institutional research programs are subject to the danger of becoming too conventional or of losing a sense of urgency with respect to their mission. We noted earlier that project grant support has been defended on the basis that it forces a research system to become more responsive. We find no fault with this argument as long as project research support remains relatively small—as long as its impact is to encourage the exploration of new opportunities within the broad research mission of an institution.

There are also other devices for offsetting geriatric tendencies in a mature research institute. The development of cost-sharing arrangements between public research institutes and clientele groups, or user representation on boards of directors or advisory committees, and use of periodic peer review panels are among the possibilities. An important factor in the case of the state agricultural experiment stations has been their location within a university environment. The interaction between graduate training and research and the opportunities to draw on professional capacity in related fields have contributed to research productivity.

Another argument which must be dealt with is whether a competitive PR support system is an effective way of taking advantage of the research capacities that exist outside of institutionally funded research programs. A major argument in favor of the new USDA project grant program is that it would be able to draw on professional resources in departments that do not receive experiment station funding and in institutions that were not part of the land grant system. An analogy often is made with the project grant programs of the National Science Foundation, which frequently supports the research of individual scientists in institutions which have very little institutional research capacity.

This argument is only partially compelling. The United States has been reasonably successful in evolving a dual system of colleges and universities in which those institutions that are capable of organizing effective graduate training and research activities are sharply differentiated from those that do not possess such capacity. The major research universities probably have greater capacity to manage efficiently a program of research grants based primarily on the quality of individual projects than a central granting agency such as the USDA or the National Science Foundation.

For the colleges and universities which do not have substantial graduate programs, faculty research must be justified primarily on the basis of contribution to the viability of the teaching programs. A limited commitment of faculty effort to scholarship and research contributes to the vitality of undergraduate teaching programs. Even in institutions that are primarily committed to an undergraduate education mission, our experience on university and agency research review panels leads us to believe that institutional support for a program of small grants would be more efficient than a grant program that is centralized in a Washington agency.

In our view, the current argument about the merits of institutional (IR) and project (PR) research support more appropriately is cast in terms of the relative mix of the two systems of support than in the absolute merits of either system. We do, however, insist that the issue of efficiency in the allocation and use of research resources is important. The productivity of agricultural research judging from historical rates of return has been high. This places a heavy burden on those who would argue for

the shift of resources from institutional to project support to demonstrate that such a shift would either enhance the productivity of the existing level of research support or draw substantial new resources into the agricultural research system.

The Role of the Marital Deduction in Planning Intergenerational Transfers

David Reinders, Michael Boehlje, and Neil E. Harl

The marital deduction is an important and commonly used estate-planning tool. The optimal marital deduction should be chosen to minimize the present value of the tax outlays at the deaths of both the husband and wife given the expected growth rate, the appropriate discount rate, the expected time of death of the surviving spouse, the distribution of wealth between the spouses, and the total wealth of both spouses. The typical practice of claiming the maximum marital deduction allowed by law or the amount that just reduces the tax liability of the decedent to zero does not necessarily produce an optimal result.

Key words: estate planning, estate taxation, linear programming, optimal marital deduction.

For individuals and couples owning sufficient property for their estates to incur estate taxation, planning for the disposition of their property during life and after death may include attempts to minimize federal unified gift and estate (and state death tax) liabilities. For those unmarried at the time of death, important strategies for reducing the federal estate tax liability include claiming the allowable deductions and credits, using special provisions such as use valuation of real property and alternate date of valuation to determine the value at which property is included in the gross estate, and making gifts during life.[1] (See also Case, Barnett, for other post-mortem estate-planning techniques.) The allowable deductions at death include funeral costs, medical expenses, costs of administering the estate, outstanding debts and obligations of the decedent, an orphan's deduction, and a charitable deduction. Credits available at death include the unified credit, credit for state death taxes paid, credit for gift taxes paid, and a credit on prior transfers.

Planning involving married couples may include an additional factor, the marital deduction. The marital deduction is available only for property passing to a surviving husband or wife; it is not available in the estate of a widow, widower, or unmarried person. For deaths after 1976, the maximum marital deduction can be the greater of $250,000, or 50% of the adjusted gross estate, but under no circumstances can it exceed the amount of property passing to the surviving spouse.[2] Furthermore, for property to qualify for the marital deduction, the surviving spouse must have sufficient control over the assets received so that the marital deduction property (if retained) will be included in his (her) estate at the subsequent death. Two common examples of property interests that would qualify for the marital deduction are fee simple and a life estate plus a general power of appointment (IRC § 2056[b][5]).

Thus, the marital deduction becomes a key decision variable in estate planning for married couples. This article provides a mathematical and computational base for determining the optimal-size marital deduction.

David Reinders is a reseach associate in economics; Michael Boehlje is a professor of economics; and Neil E. Harl is a Charles F. Curtiss Distinguished Professor in Agriculture and professor of economics, Iowa State University. Harl is also a member of the Iowa bar.

Journal Paper No. J-9711 of the Iowa Agriculture and Home Economics Experiment Station, Ames. Project No. 2291.

[1] Every donor is entitled to an annual exclusion of up to $3,000 per beneficiary per year without paying federal gift tax. For gifts made by a husband and wife, the exclusion becomes $6,000 per beneficiary per year. Making gifts to noncharitable beneficiaries larger than the annual exclusion results in use of the unified credit which could have been used at death.

[2] The maximum available federal estate tax marital deduction may be less than the greater of $250,000, or 50% of the decedent's adjusted gross estate if gifts are given to a spouse. If the federal gift tax marital deduction claimed exceeds what the gift tax marital deduction would have been, had it been set at 50% of the amount reported as a gift to the spouse, the excess is subtracted from the allowable estate tax marital deduction I.R.C. § 2056.

Conceptual Model

The marital deduction has received considerable attention in the literature. Many analysts have identified the marital deduction as one of a number of estate-planning tools available (Boehlje and Eisgruber; Levi and Allwood; Harl 1977; Harl and Boehlje) and the dimensions to be considered in choosing the optimal marital deduction have been described (Harl; Harl and Boehlje; and Harl 1979a,b). Some researchers have addressed the question of the correct legal terminology to use in structuring the marital deduction as part of the process of drafting the will (Barnes; Thomas, Esperti, Katz); others have investigated how the marital deduction share should be funded (Brode; Harl 1979a,b,c, 1977). While some analysts have recognized that it is not always advantageous to utilize the maximum marital deduction allowable (Allington; Thomas, Esperti, Katz), these studies have not considered explicitly such economic concepts as economic optimization and the time value of money.

Analytical Framework

The purpose of this article is to provide an analytical and empirical framework to determine the optimal marital deduction; a framework that explicitly considers in a present value context the appreciation in value of assets over time, the age and health of the survivor, the distribution of wealth between the spouses, and the combined estate size of both spouses.[3]

The role of the marital deduction is illustrated in figure 1. Assume a husband and wife have estates defined as A_1 and A_2 and that the spouse owning estate A_1 dies first at time t. The marital deduction property (MD) passes to the surviving spouse in fee simple or at least in trust or a life estate plus a general power of appointment. The nonmarital deduction property typically passes to the survivor for life in trust or in a legal life estate.[4] At the first death,

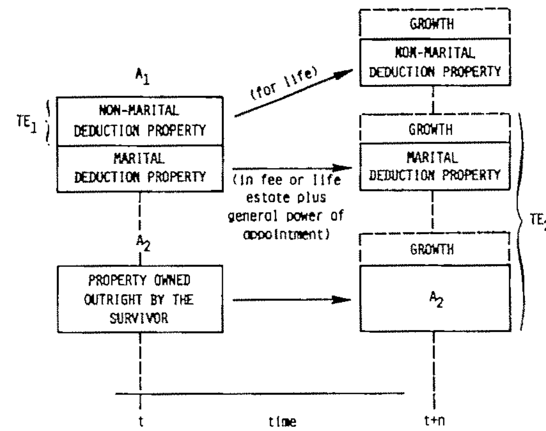

Figure 1. The marital deduction

only the nonmarital deduction property is taxed (TE_1). At the death of the survivor—time $t + n$—all property owned outright by the survivor (A_2) plus the earnings and growth in value on that property and the marital deduction property plus the earnings and growth in value on it (TE_2) are taxed. The nonmarital deduction property plus the earnings and growth in its value passes to the remaindermen.

Harl (1979a,b) has identified two basic estate-planning models. In Harl's Model I, property ownership is concentrated, usually in the husband's name, with the husband's will leaving a portion of his property (usually the maximum allowable marital deduction) to his wife in fee simple or in a life estate with a general power of appointment. The remaining property is left to the wife for life (in trust or legal life estate). For this model to minimize the estate tax liability, the husband must cooperate and die first.

In Harl's Model II, property ownership is divided equally between the spouses, with each spouse leaving his or her property to the other for life. This plan deliberately avoids qualifying property for the marital deduction and does not depend upon a particular order of death for its successful operation.

In addition, Harl has outlined (in his Modified Model II plan) the conceptual basis to accomplish the objective of minimizing the present value of the taxes and estate settlement costs (or maximizing wealth) after the deaths of both spouses.[5] In this plan property

[3] Funding of the marital deduction is important when the assets have different growth rates. But before this issue of optimal funding can be answered, the optimal size must be determined. Therefore, we assume all assets have the same growth rate and leave the questions of optimal funding for later research. Other related areas of investigation beyond the scope of this article include the interactions between the marital deduction and *inter-vivos* gifting, ten- and fifteen-year installment payment deferrals, and special use valuation.

[4] Alternatively the nonmarital share may pass directly to the children. The important point is that the nonmarital share must not be left with such ownership rights as would make it includable in the gross estate of the surviving spouse.

[5] Provided that the rates of growth on the property in the marital deduction share, the nonmarital deduction share and the property

ownership is divided equally between the spouses during life. At the first death, the marital deduction (not necessarily at its maximum) is used to decrease the taxable estate of the first to die and increase the taxable estate of the survivor. The size of the marital deduction becomes the key variable in implementing a Modified Model II plan, given the amount of property and ownership distribution between the spouses.

Developing balanced estates produces a property ownership pattern most likely to be compatible with tax minimization or wealth maximization. However, there are a number of reasons why balancing estate sizes during life may not be desirable or possible for the married couple. The spouse owning the majority of the property may not be willing to relinquish control, or the spouse with the smaller amount may not be willing to assume control. Also, gift tax consequences of transferring property during life may be prohibitive. And even if a well-designed gifting plan is initiated which would balance the estates at its completion, the fruits of the plan may never be realized because there is not sufficient time before the first death. In these cases, utilization of an optimal marital deduction is equally as important as in the Modified Model II plan, because the size of the marital deduction significantly influences tax liabilities at both the first and second death.

The Optimization Model

The optimal size of the marital deduction—whether that be none, the maximum allowed by law, or some value in between—depends upon the tax treatment of the property at both deaths and the desire to minimize these tax liabilities (maximize wealth transferred) as well as accomplishing other estate-planning goals. For purposes of our analysis, we will assume that minimizing the present value of the total tax outlays at both deaths is consistent with other family goals.[6] Thus, the optimal marital deduction should be chosen to minimize the present value of tax outlays given (*a*) the expected growth of assets between deaths, (*b*) the expected discount rate appropriate to the estate of the first to die for the period between deaths, (*c*) the expected time of death of the surviving spouse, (*d*) the distribution of wealth between the spouses at the time of the first death, and (*e*) the combined estate sizes of the spouses. This is a slight restatement of the five variables identified by Harl (1979a,b).

Specifically, the optimal marital deduction can be determined as that deduction (MD) which

$$(1)\quad \text{Minimizes } K = TAX_1 + \frac{TAX_2}{(1 + R)^N},$$

subject to: $TAX_1 \geq 0$, $TAX_2 \geq 0$, $0 \leq MD \leq$ maximum allowed by law, and R, G, ≥ 0, where

$$(2)\quad TAX_1 = t_1(A_1 - MD) - UC_1 - SDC_1,$$

$$(3)\quad TAX_2 = t_1[(A_2 + MD)(1 + G)^N] - UC_2 - SDC_2 - PTC,$$

$$(4)\quad SDC_1 = t_2(A_1 - MD),$$

$$(5)\quad SDC_2 = t_2[(A_2 + MD)(1 + G)^N], \text{ and}$$

$$(6)\quad PTC = (LE_c)(\%N)(TAX_1),$$

where

TAX_1 is the tax due at the death of the first spouse;

TAX_2, tax due at the death of the second spouse;

R, appropriate expected discount rate;

N, expected number of years between deaths based on actuarial data;

MD, marital deduction taken;

G, weighted average expected growth rate;

A_1, adjusted gross estate of the first spouse to die;

A_2, adjusted gross estate of the second spouse to die;

t_1, federal unified estate and gift tax rate schedule;

UC_1, unified credit available at the first death;

SDC_1, state death tax credit at death one;

UC_2, unified credit available at death two;

SDC_2, state death tax credit at death two;

t_2, federal credit for state death taxes paid rate schedule;

PTC, prior transfer credit;

LE_c, present interest of the surviving spouse in the property of the nonmarital deduction trust (This coefficient is given by law based upon the age of the surviving spouse at the time of the first death.);

owned outright by the surviving spouse are equal, the maximization of wealth passing to the heirs after both deaths is equivalent to the minimization of the present value of the tax outlays over both deaths.

[6] Goals and objectives of the family which are in conflict with the optimal marital deduction can be incorporated into the analysis by imposing additional constraints. For simplicity, we will only address unconstrained optimization in this analysis.

$\%N$ is the percentage of the prior transfer credit available as a result of the time which has passed between deaths. The percentage schedule is:

Time (years) between Deaths	$\%N$
0–2	100
2–4	80
4–6	60
6–8	40
8–10	20
over 10	0

The objective is to minimize the present value of the taxes paid at both deaths, subject to the constraints that the taxes paid at each death must be positive or zero and that the marital deduction must be between zero and that allowed by law. The tax due at the first death is defined [eq. (2)] as the adjusted gross estate of the first spouse to die minus the marital deduction times the appropriate tax rate minus the unified and state death tax credits.[7] The tax due at the second death [eq. (3)] is calculated as the adjusted gross estate of the surviving spouse plus the marital deduction compounded at the expected growth rate times the appropriate tax rate minus the unified, state death tax, and prior transfer credits. The state death tax credits are a function of the estate size [eq. (4) and (5)], and the prior transfer credit is a function of the surviving spouse's present interest in the nonmarital deduction property, the elapsed time between deaths, and the tax due at the death of the first spouse to die [eq. (6)].

The size of the marital deduction to be claimed should not be decided until the time of the first death. This is the latest point at which the decision can be made and the time when the surviving spouse, the heirs, and legal counsel have the best information about the relevant variables. This decision can be implemented by a formula clause which takes into account changes in circumstances or through use of a disclaimer clause in the decedent's will (Harl 1979a,b,c; Covey; Glasser).

Because the tax and credit rate structures are composed of a series of linear rates, the problem of equations (1)–(6) can be solved as a linear programming problem, assuming the number of years between deaths can be appropriately estimated using mean values from life expectancy tables. At first glance the stochastic dimension of the time of death would imply that a deterministic solution procedure such as linear programming would not be applicable to this problem. However, the problem only contains one stochastic event—the expected number of years between deaths—because the choice of an optimal marital deduction can be delayed until the death of the first spouse to die. To determine the sensitivity of the choice of the optimal marital deduction to expectations concerning the number of years between deaths (as determined by life expectancy and health of the survivor at the death of the first spouse to die), the number of years between deaths is parameterized in the empirical analyses from zero to twenty years. As will be shown later in the section on cost of choosing the wrong marital deduction, not knowing with certainty the time of death of the survivor does not detract from the usefulness of this model or the results generated.

Empirical Results

The specific combinations of parameters included in the analyses are summarized in table 1. For a combined estate size (husband and wife) of $500,000, wealth distributions of $200,000 owned by the first spouse to die and

Table 1. Combinations of Parameters Analyzed

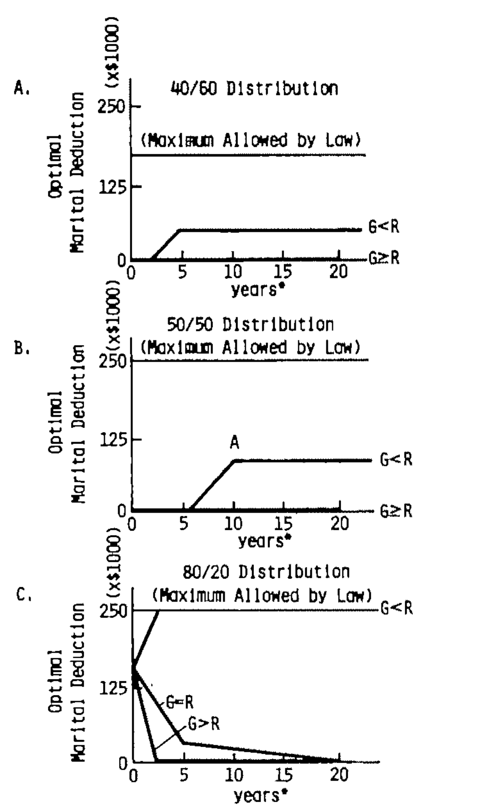
Combined Estate Size	Distribution between Spouses: Estate of First Spouse to Die (A_1)	Estate of Surviving Spouse (A_2)
	$	$
$ 500,000	200,000	300,000
	250,000	250,000
	400,000	100,000
$ 750,000	300,000	450,000
	375,000	375,000
	600,000	150,000
$1,000,000	200,000	800,000
	400,000	600,000
	500,000	500,000
	800,000	200,000

Note: Each distribution of property between spouses was run for three combinations of growth (G) and discount (R) rates ($G = 5\%$ and $R = 8\%$, $G = 8\%$ and $R = 5\%$, and $G = 8\%$ and $R = 8\%$). Each configuration of combined estate size, distribution between spouses, growth rate, and discount rate was then analyzed for values of N between zero and twenty years.

[7] The adjusted gross estate is the gross estate reduced by legal fees, court costs, and burial expenses. Because these settlement costs do not influence the size of the optimal marital deduction, they are ignored for the sake of simplicity.

$300,000 owned by the second spouse; $250,000 owned by each; and $400,000 owned by the first spouse to die and $100,000 owned by the surviving spouse were analyzed. Each of these situations was evaluated for three combinations of growth (G) and discount (R) rates—$G = 5\%$ and $R = 8\%$, $G = 8\%$ and $R = 8\%$, and $G = 8\%$ and $R = 5\%$. These growth and discount rates were selected as representative of after-tax rates for a planning horizon of fifteen to twenty years. These rates may appear somewhat conservative for shorter planning horizons of, say, one or two years but were held constant so that comparisons can be made over planning horizons of different lengths. Additionally, it is the relative values of G and R that are important, not the absolute magnitudes of these rates. Finally, the expected number of years until the second death (N) was incremented from zero to twenty years. The results of these situations are graphically portrayed in figures 2A–2C.

With a combined estate size of $750,000, estate distributions between the decedent and surviving spouse of $300,000 and $450,000; $375,000 and $375,000; and $600,000 and $150,000, respectively, were analyzed, using the three combinations of growth and discount rates as above while incrementing N from zero to twenty years. The results of these combinations of parameters are presented in figures 3A to 3C. The last combined estate size selected for this analysis was $1,000,000 divided between the decedent and surviving spouse, respectively, as $200,000/$800,000; $400,000/$600,000; $500,000/$500,000; and $800,000/$200,000. Each of these analyses, again, was completed for the combinations of growth rates, discount rates, and expected number of years until the second death described above. The graphical results for this set of parameters are presented in figures 4A through 4D.



*Expected number of years until the second death are based on actuarial data.

An Illustration

Table 2 illustrates the results for a combined estate of $500,000, with $200,000 included in the estate of the first spouse to die and $300,000 owned by the surviving spouse. The optimal marital deduction that minimizes the present value of the taxes at both deaths is presented for three selected values of expected life assuming an expected growth rate of 5% and discount rate of 8%.

If the surviving spouse is not expected to

Table 2. Numerical Example for a $500,000 Combined Estate

	Expected Number of Years until Second Death		
	<1	5	15
		$	
First death:			
Adjusted gross estate	200,000	200,000	200,000
Less: optimal marital deduction	0	50,000	51,370
Taxable estate	200,000	150,000	148,630
Tentative federal estate tax	54,800	38,800	38,389
Less: unified credit	38,000	38,000	38,000
Less: credit for state death taxes paid	1,200	400	389
Federal estate tax due	15,600	400	0
Present value of federal estate tax	15,600	400	0
Second death:			
Adjusted gross estate (at increased value)	300,000	446,696	730,462
Taxable estate	300,000	446,696	730,462
Tentative federal estate tax	87,800	137,677	241,071
Less: unified credit	38,000	47,000	47,000
Less: credit for state death taxes paid	3,600	8,600	19,587
Less: prior transfer credit	400	38	0
Federal estate tax due	45,800	82,259	174,484
Present value of federal estate tax	45,800	55,984	55,004
Present value of taxes at both deaths	61,400	56,384	55,004

Note: Expected growth rate = 5%; appropriate discount rate = 8%.

live out the year (leftmost column in table 2), the federal estate tax due at the first death is $15,600 based on an adjusted gross estate of $200,000, an optimal marital deduction of $0, and a taxable estate of $200,000. All property owned by the first spouse to die, net of estate taxes, passes to the surviving spouse in a legal life estate or life estate in trust and therefore does not increase the survivor's estate at the second death. At the surviving spouse's death, the federal estate tax due net of available credits is $45,800, based on an adjusted gross estate and taxable estate of $300,000. The present value of taxes at both deaths is $15,600 + $45,800 = $61,400. If a marital deduction is taken at the first death, the increase in tax due at the second death will more than offset the decrease in tax at the first death.

When the surviving spouse is expected to die five years after the first spouse (middle column, table 2), the federal estate tax due at the first death is $400 on a taxable estate of $150,000 (calculated as the adjusted gross estate of $200,000 less an optimal marital deduction of $50,000). The surviving spouse receives $50,000 in a life estate with a general power of appointment and $149,600 ($150,000 taxable estate less $400 tax) with only a life interest. After five years, the $300,000 adjusted gross estate of the surviving spouse and the $50,000 of marital deduction property have grown to $446,696, compounded annually at 5%. This adjusted gross estate of $446,696 produces a federal estate tax of $82,259, after available credits. The total present value of the taxes paid at both deaths is $56,384, which is the minimum possible (for $N = 5$ years, $G = 5\%$, and $R = 8\%$).

When the surviving spouse is expected to die fifteen years after the first spouse (right column, table 2), the optimal marital deduction is $51,370, which results in a taxable estate of $148,630. The credits available at the first death are just sufficient to offset the tentative federal estate tax, resulting in no tax due at the first death. The surviving spouse receives the $51,370 of marital deduction property outright and the remaining $148,630 with only a life interest. Fifteen years later the $300,000 of property the surviving spouse owns outright and the $51,370 of marital deduction property have grown to $730,462. This results in a federal estate tax due at the second death of $174,484, which, when discounted, results in a present value of $55,004. Because there was no tax paid at the first death, the total present value of taxes at both deaths is also $55,004.

Interpretation of Graphical Results

Figure 2A is constructed for a combined estate of $500,000, with $200,000 owned by the first spouse to die and $300,000 owned by the survivor. The expected number of years from the first death until the second death is graphed along the horizontal axis. The optimal marital deduction is graphed in thousands of dollars along the vertical axis. The maximum marital deduction allowed by law is $200,000 (the property owned by the decedent), and the minimum marital deduction is $0. There are three curves on this as well as the other graphs. One is for an expected growth rate (G) which is less than the discount rate (R); the second is for an expected growth rate larger than the discount rate; and the third is for an expected growth rate equal to the discount rate. For this estate size and distribution, if the growth rate is less than the discount rate and the surviving spouse is expected to live for less than two years, the optimal marital deduction which should be taken is zero dollars. With a zero marital deduction, all of the property of the first spouse to die is passed to the surviving spouse with only a life interest.

If the surviving spouse is expected to live for more than five years, the optimal marital deduction which should be taken is $51,370. A marital deduction of this size reduces the taxable estate of the decedent to $148,630 and increases the estate of the surviving spouse to $351,370. The unified credit of $38,000, available for deaths in 1979, and the credit for state death taxes paid of $389 are just sufficient to offset the tentative federal estate tax due at the first death. The surviving spouse would receive $51,370 outright and the remaining $148,630 with only a life interest.

The other two curves in figure 2A assume a growth rate greater than the discount rate and a growth rate equal to the discount rate. For these sets of parameters the two curves are superimposed upon the horizontal axis. That is, if the growth rate equals or exceeds the discount rate, the marital deduction that minimizes the present value of the taxes at both deaths is zero regardless of how long the surviving spouse is expected to live. The reason for an optimal marital deduction of $0 is that any marital deduction greater than zero increases the present value of the tax at the

second death by a larger amount than it reduces the present value of the tax at the first death. The graphs in figures 2, 3, and 4 can be interpreted in a similar manner.

Impact of Combined Estate Size

As the size of the combined estates increases from $500,000 to $750,000 to $1,000,000, the present value of the taxes paid at both deaths also increases, assuming a fixed proportionate distribution of property between spouses. If the growth rate is less than the discount rate and the surviving spouse is expected to live at least five years, the optimal marital deduction increases with increasing combined estate size. The optimal marital deduction is zero regardless of the combined estate size and distribution between spouses when the growth rate exceeds the discount rate and N exceeds five years. When the growth rate equals the discount rate, the optimal marital deduction is zero for all sizes of combined estates unless the first spouse to die owns a disproportionately large share of the estate (such as 80% in figs. 2C, 3C, and 4D). When the decedent owns 80% of the combined estates, the optimal marital deduction is always some value less than the optimal deduction for G less than R and greater than the optimal for G greater than R. The optimal marital deduction varies with the particular value of $G = R$ and with the number of years between deaths. For very low values of $G = R$ (2% or 3%), the optimal deduction is larger than that shown in figures 2C, 3C, and 4D. For values of $G = R$ above 8%, the optimal deduction is smaller than that shown in figures 2C, 3C, and 4D.

Impact of Estate Distribution

With a combined estate size of $500,000 (figs. 2A–2C), a growth rate smaller than the discount rate and N greater than ten years, the optimal marital deduction increases from $51,370 when the decedent owns $200,000 of the combined estate (fig. 2A) to $101,370 when the decedent owns $250,000 of the combined estate (fig. 2B). In both situations the decedent's taxable estate is reduced to $148,630, and the marital deduction taken is less than the maximum allowed by law. When the decedent owns $400,000 of a $500,000 combined estate (fig. 2C), the optimal marital deduction is constrained by the maximum allowed by law; if the decedent could, he or she would take an even larger marital deduction. If the upper limit on the marital deduction were not constrained by law, the optimal deduction would be $251,370, because this would reduce the decedent's taxable estate to $148,630.

If G is greater than R and N is greater than two years (again assuming a combined estate size of $500,000), the optimal marital deduction is zero for all distributions between spouses. This is also the case where the growth rate equals the discount rate except when the decedent owns 80% of the combined estate. In this latter situation the optimal marital deduction varies over time as shown in figure 2C.

The optimal marital deduction follows a similar pattern for combined estate sizes of $750,000 and $1,000,000, as summarized for the $500,000 estates. That is, if G is less than R and N is greater than ten years, the optimal marital deduction is the smaller of the maximum allowed by law and the amount which will result in no tax being paid at the first death through use of the credits. The optimal marital deduction is zero for G greater than R and N greater than four years for all estate sizes and distributional schemes considered. When the growth rate (G) equals the discount rate (R), the optimal marital deduction will be zero unless the decedent owns 80% of the combined estate. In this situation, the optimal marital deduction will fall somewhere in between the legal boundaries as shown in figures 3C and 4D.

Impact of Time

The passage of time (in terms of the expected life of the surviving spouse) affects the optimal marital deduction in two ways. For the first ten years between deaths, a prior transfer credit is available at the second death for taxes paid at the first death. This makes paying taxes at the first death relatively more attractive because it generates an additional credit which can be employed at the second death. The second impact is the compounding effect that time has on both the discount factor and the growth factor.

Because of these two effects of time, the optimal marital deduction may vary a great deal during the first ten years between deaths depending upon the values for the other parameters. As N increases beyond ten years, the optimal deduction remains constant except in the cases where $G = R$ and the decedent

owns 80% of the combined estate (figs. 2C, 3C, and 4D). For example, with a combined estate of $1,000,000 distributed equally between spouses and G less than R (fig. 4C), the optimal marital deduction is zero for N between zero and five years. The optimal deduction increases from zero to the maximum allowed by law as N increases from five to ten years. Then, for all values of N greater than ten years, the optimal marital deduction remains at the maximum allowed by law of $250,000. Similar results are obtained for the other estate sizes and distributions.

Impact of the Discount Rate and Rate of Growth

Of the variables which influence the size of the optimal marital deduction (combined estate size, distribution between spouses, expected years between deaths, growth rate and discount rate), the growth rate (G) and the discount rate (R) are the most crucial. With the exception of the case where the decedent owns 80% of the combined estate and G equals R, it is the relationship of G to R and not their absolute values which is the most important in determining the optimal marital deduction. If the growth rate is larger than the discount rate and N exceeds four years, the optimal marital deduction is zero under all combined estate sizes and all interspousal distributional schemes evaluated. If the growth rate is smaller than the discount rate and N exceeds ten years, the optimal marital deduction is the maximum allowed by law or the amount which just reduces the federal estate tax liability at the death of the first spouse to zero, whichever is smaller. If the growth rate equals the discount rate, the optimal marital deduction is zero under all combined estate sizes unless the spouse who dies first owns a disproportionately large share of the estate (such as 80% in this analysis). In this situation the optimal marital deduction falls somewhere between the optimal deduction for G less than R and the optimal for G greater than R. Just where the optimal deduction falls depends on the absolute value of $G = R$.

Cost of Choosing the Wrong Marital Deduction

For any point on the curves of figures 2, 3, and 4, graphs such as those presented in figures 5, 6, and 7 can be constructed to indicate the cost

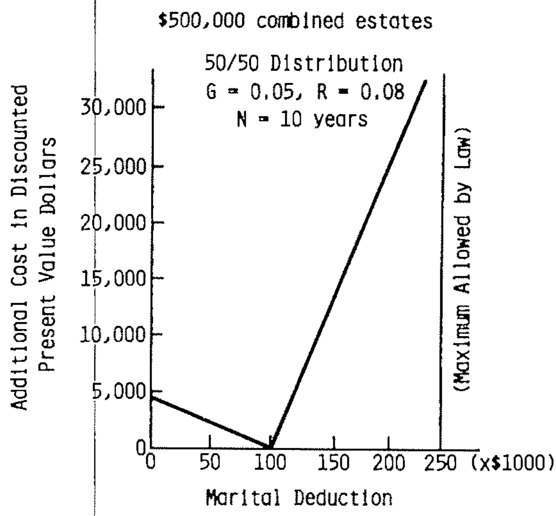

Figure 5. Cost of choosing the wrong marital deduction (point A on figure 2B)

of choosing the wrong marital deduction. Points selected for further analysis are A on figure 2B (shown in fig. 5) and B and C on figure 4C (figs. 6 and 7, respectively).

On each of the graphs in figures 5 through 7, the horizontal axis measures the amount of marital deduction actually taken. The vertical axis measures the additional cost in discounted present value dollars of the taxes paid at both deaths from taking a marital deduction other than the optimal. These graphs show the cost of choosing the wrong marital deduction, or, conversely, the value of using the optimal as opposed to some other marital deduction such as the maximum allowed by law.

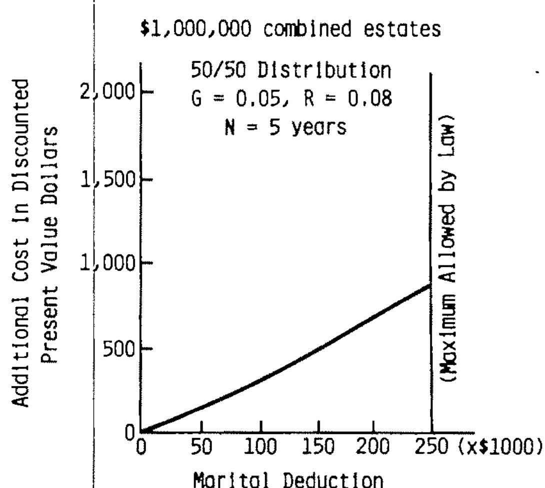

Figure 6. Cost of choosing the wrong marital deduction (point B on figure 4C)

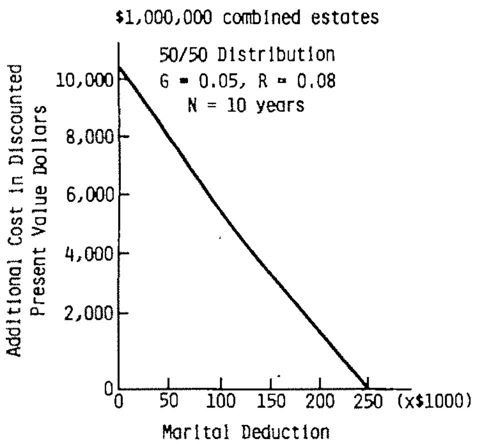

Figure 7. Cost of choosing the wrong marital deduction (point C on figure 4C)

With a combined estate of $500,000, a growth rate less than the discount rate and the expected life of the surviving spouse equal to ten years, the optimal marital deduction is $101,370 (fig. 2B). If, instead, a marital deduction of only $50,000 is taken, the present value of the taxes paid at both deaths is increased by $2,388 over the minimum tax liability (fig. 5). If a marital deduction of zero is taken, the present value of taxes is increased by $5,336. On the other hand, a $150,000 marital deduction results in an increase of $12,050 in the present value of the taxes paid at both deaths. If the maximum marital deduction allowed by law of $250,000 is taken, the present value of taxes paid increases by $37,188. The reason it is more costly to over-qualify rather than under-qualify for the marital deduction is that with over-qualification, full use is not being made of the credits available at the first death.

With a combined estate of $1,000,000 owned equally by the spouses, a growth rate less than the discount rate and the expected time between deaths of five years (fig. 6), the optimal marital deduction under these circumstances is zero dollars (fig. 4C). If the actual marital deduction taken was $50,000, the present value of taxes would increase by $87 (fig. 6). If the maximum marital deduction allowed by law is taken, the cost of making this mistake is $694.

For the same set of circumstances as described above, with the exception of the time between deaths of ten rather than five years (fig. 7), the optimal marital deduction is $250,000 (fig. 4C). If the actual marital deduction taken is $200,000, the additional present value of taxes is $1992 (fig. 7). If no marital deduction is taken, the additional cost in terms of taxes paid is $10,502.

Note that with this estate size and distribution and an expected life of five years (fig. 6), missing the optimal marital deduction by $250,000 increases the present value of taxes by only $694 (from $198,927 to $199,621). However, with an expected life of ten years (fig. 7), the cost of a mistake in taking the wrong marital deduction is considerably larger. The present value of taxes increases by $10,502, from $188,522 at the optimal level to $199,024, when no marital deduction is taken. The longer the expected life of the surviving spouse, the more costly is a mistake in taking the wrong marital deduction. Thus, in situations such as described here, it is more important to choose the optimal marital deduction when the expected life of the surviving spouse is ten years than when the expected life is only five years. This is a direct result of the compounding effects of time on the expected growth rate and discount rate and the influence of these parameters on the optimal marital deduction.

As noted earlier, at the time the decision as to the optimal marital deduction must be made, the one variable which cannot be ascertained with certainty is the expected remaining life of the surviving spouse. To be sure, the death of the surviving spouse can be estimated from actuarial data as has been done in this analysis. Or if the health of the surviving spouse is abnormally poor for his or her age, a subjective estimate of life expectancy may be made based upon the state of health. However, as shown in figures 6 and 7, taking any size marital deduction, even the maximum allowed by law, does not result in a very costly error if the surviving spouse dies within ten years of the decedent. If the surviving spouse dies more than ten years after the decedent, the cost of taking the wrong marital deduction is much greater. However, the optimal marital deduction remains constant (assuming a particular estate size, distribution, growth, and discount rates) if the surviving spouse dies ten or more years after the decedent. Therefore, even though the cost of making a mistake becomes larger as the time between deaths increases beyond ten years, any deviation between the actual date of death and the expected date of death results in no error in the choice of the optimal marital deduction.

Conclusions

Only selected combined estate sizes and distributional schemes have been analyzed, but due to the symmetry of the analysis—both spouses face the same unified federal gift and estate tax rate schedule and the same credit schedules—the results presented here can be generalized for estates of all sizes.[8] These generalizations are as follows:

(*a*) If the expected growth rate is less than the appropriate discount rate, the optimal marital deduction will be the smaller of the maximum allowed by law, or the marital deduction which makes full use of all credits available and results in no federal estate tax at the first death.

(*b*) If the expected growth rate is greater than the appropriate discount rate, the marital deduction which should be taken is zero.

(*c*) If the expected growth rate equals the discount rate and if the first spouse to die does not own a disproportionately large share of the combined estate, the optimal marital deduction that should be taken is zero. If the first spouse to die does own a disproportionately large share of the combined estate, it may be necessary to perform an analysis similar to the one presented here to determine the optimal marital deduction.

The one variable the estate planner cannot ascertain with certainty is the expected life of the surviving spouse. The stochastic nature of this variable may result in some error if the above generalizations are used. However, drawing values for the expected life variable from actuarial tables or from subjective estimates of state of health produces a marital deduction amount that is, in a high proportion of instances, closer to the optimal level than the common practice of claiming the maximum allowed by law or the maximum marital deduction which will just reduce the tax liability of the decedent to zero, as is the typical practice.

The choice of the optimal marital deduction is only one example of the opportunity to apply economic concepts and optimization procedures in estate planning. Additional applications include the optimal funding of the marital deduction, the optimal distribution of property ownership prior to the death of either spouse, the optimal gifting program among spouses and heirs and the interactions between the marital deduction at death, lifetime gifts, installment payment of tax, special use valuation and the income tax basis of estate property. Further research to evaluate these issues is ongoing.

[Received August 1979; revision accepted November 1979.]

[8] This symmetry holds only if the tax laws do not change during the period between deaths.

Attitudes toward Risk: Experimental Measurement In Rural India

Hans P. Binswanger

Attitudes toward risk were measured in 240 households using two methods: an interview method eliciting certainty equivalents and an experimental gambling approach with real payoffs which, at their maximum, exceeded monthly incomes of unskilled laborers. The interview method is subject to interviewer bias and its results were totally inconsistent with the experimental measures of risk aversion. Experimental measures indicate that, at high payoff levels, virtually all individuals are moderately risk-averse with little variation according to personal characteristics. Wealth tends to reduce risk aversion slightly, but its effect is not statistically significant.

Key words: India, psychological experiments, risk aversion, semi-arid tropics.

The research reported here was carried out in the semi-arid, tropical areas of India, characterized by high climatic risk for agriculture. It was initiated to determine whether differences in behavior between farmers of different wealth levels are the consequence of different attitudes towards risk or of different constraint sets such as limitations on credit or on access to modern inputs. This question is of considerable policy importance because policy presumably can affect credit and other constraints faced by low income farmers more easily than their attitudes toward risk. The basic approach is experimental. It measures attitudes by observing the reactions of individuals to a set of actual one-period gambles. It must be recognized that extrapolating the findings of such an approach to real farm decisions may face theoretical challenges.[1]

Earlier experimental work on measurements of attitudes toward risk was carried out primarily by experimental psychologists and is reviewed by Luce and Suppes. Where actual gambles were involved, payoffs and sample sizes were small. In this study, payoffs varied from very low levels to levels exceeding the monthly incomes of unskilled rural laborers. The total sample size was 330.

Agricultural economists have measured parameters of utility functions by simulated gambling situations rather than actual ones. Officer and Halter, O'Mara, and Dillon and Scandizzo used approaches based on utility theory and elicitation of certainty equivalents. Kennedy, instead, used a method based on focus loss. Only Dillon and Scandizzo used simulated farming problems rather than pure simulated gambles.

The Experimental Sequence

The experimental method based on one-period gambles was developed after results of a survey using the Dillon-Scandizzo approach suggested that their method was subject to interviewer biases (fourth section).[2] To overcome

Hans P. Binswanger is an associate of the Agricultural Development Council, stationed at the Economic Growth Center, Yale University.

ICRISAT Journal Article Approval No. 116.

The experiment on which this paper is based was carried out while the author was stationed at the International Crops Research Institute for the Semi-Arid Tropics, Hyderabad, India, and with its generous support.

The author would like to thank B. C. Barah, R. D. Ghodake, S. S. Badhe, M. J. Bhende, V. Bhaskar Rao, T. Balaramaiah, N. B. Dudhane, Rekha Gaiki, K. G. Kshirsagar, Madhu Nath and Usha Rani, who helped in carrying out the experiment. James Roumasset, University of Hawaii, and an anonymous referee made particularly helpful comments on an earlier draft.

[1] Masson and Roumasset (1978b) point out that under fairly restrictive assumptions, a utility function in "one-period money" may be viewed as an indirect utility function that reflects the interaction of a lifetime utility function of consumption with borrowing and lending opportunities. An individual who is risk-neutral with respect to utility function in lifetime income may exhibit an apparently risk-averse indirect utility function for one-period money because of capital market imperfections, and therefore the attempt to separate attitudes from constraints may be impossible using one-period gambles.

[2] The author is personally indebted to John Dillon and Pasquale Scandizzo for encouraging him to start work on risk aversion with large samples. He is indebted also to J. G. Ryan and Matthias von Oppen for later encouraging a shift to experimental methods.

moral problems confronting low income people involved in gambling, the gambling was limited so that the worst possible outcome was a zero gain, and it thus involved gifts to the respondents. Because many respondents were illiterate, the experiment had to be simple. Also, because farming decisions are often taken on an annual or crop-cycle basis and in consultation with relatives and friends, the experiment was designed to allow long periods for reflection and opportunities for consultation.

Only minimal theoretical commitments were to be made at the outset. The set of choices should be ranked as more or less risky in a unique way, almost regardless of the definition of risk one might want to adopt. (For a review of problems of defining risk, see Roumasset 1978a.) The subjects were not to be confronted with any budget constraints that would rule out certain choices. One cannot, in measuring pure attitudes to risk, propose games to individuals for which the worst possible loss exceeds their current cash holdings. If one does, he may measure the impact of a cash- or budget-constraint rather than the pure attitudes towards risk (Masson, Lipton). As far as possible, respondents should perceive the same probabilities; therefore, the game was based on coin tosses.

Table 1 explains the basic method. Several days ahead of any given game, individuals were given forms (which they could keep) with the numbers of panel A on table 1. They had to choose from alternatives O to F. Once they chose, a coin was tossed and they got the left-hand amounts if heads came up or the right-hand amount if tails came up. An individual who chose O simply got Rs.50; i.e., participation in the game resulted in an automatic and sure increase in wealth by Rs.50. An individual choosing C received Rs.30 on head and Rs.150 on tail. By not choosing O he stood to lose Rs.20, but could gain Rs.100. Compared to B, which was more relevant, the potential losses and gains in going to C were Rs.10 and Rs.30, respectively. Finally, by choosing F the individual received either no money or Rs.200; F had the same expected return as E, but a higher variance, so only a risk-neutral or risk-preferring individual would make the step from E to F.

At the simplest level the choice of any alternative O to F classified the individuals into a risk aversion class to which a name was given to simplify discussion. Interpreted in the framework of expected return-variance analysis (which is useful when decision makers are confronted with normally distributed outcomes), the game consisted of offering individuals a set of alternatives within which higher expected returns could only be "purchased" at the cost of higher variance (or standard deviation), and this tradeoff could be measured by the slope Z in table 1. Interpreted in a utility framework, risk aversion could be measured by partial risk aversion S, which is fixed regardless of the level of payoff (Menezes and Hanson; Zeckhauser and Keeler).[3] To each risk aversion class corresponded an interval of partial risk aversion S.

[3] It is defined on a utility function U in terms of certain wealth W as follows: let M be the certainty equivalent of a new prospect and evaluate derivatives at $W + M$; then,

$$S(W + M) = -MU''(W + M)/U'(W + M),$$

Table 1. The Payoffs and Corresponding Risk Classification

Choice	Panel A: Heads—Low Payoff	Panel A: Tails—High Payoff	Risk Aversion Class	S Approximate Partial Risk Aversion Coefficient[a]	$Z = \frac{\Delta E^b}{\Delta SE}$
O	50	50	Extreme	∞ to 7.51	1 to 0.80
A	45	95	Severe	7.51 to 1.74	0.8 to 0.66
B	40	120	Intermediate	1.74 to .812	0.66 to 0.50
D^*	35	125	Inefficient		
C	30	150	Moderate	.812 to .316	0.50 to 0.33
D	20	160	Inefficient		
E	10	190	Slight-to-neutral	.316 to 0	0.33 to 0.00
F	0	200	Neutral-to-negative	0 to $-\infty$	0 to $-\infty$

[a] For reasons that are explained in Binswanger (1978c), a constant partial risk-aversion function on gains and losses was used to approximate S for the games. See footnote 4 for more details.

[b] Z is the trade-off between expected returns and standard deviation of two games.

In the experimental sequence (table 2) the individual was not presented immediately with the alternatives of table 2, called 50-rupees game; instead he went through a sequence of games and hypothetical questions at various game levels. All game levels were derived from the 50-rupees game by multiplying all amounts by a constant, which is 1/100, 1/10, and 10 for the 1/2-rupee, 5-rupee, and the 500-rupee game levels, respectively. The sequence started with five games at the Rs.0.50 level to teach participants the rules of the game and to convince them that they would receive the money when promised. To help illiterate people, the payoff structure was shown as a photograph with the sums of money to be received indicated by coins placed in each field. The photographs were handed out to each player and left with them through the entire 5- to 6-week period of the experiment.

The study was carried out in the 240 rural households included in the village level studies of the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Hyderabad, India. (For more details, see Jodha, Asokan, Ryan; Binswanger and Jodha.) These studies are located in the semiarid tropical tracts of Maharashtra and Andhra Pradesh, some of the poorer regions of India.

The average physical wealth of the households, approximately Rs.22,000 (US $2,750), is very low by international standards. But there were large variations in wealth in the sample, as indicated by a coefficient of variation of physical wealth of 137%. The average schooling level was only 2.6 years but had a coefficient of variation of 120%. Being a random sample of the entire population engaged in agriculture as laborers or farmers, variation in other personal characteristics was also large.

Up to the Rs.5 level, the sequence was played with all 240 household heads of the sample (of which 20 were women), although temporary absences from villages made some of the sequences incomplete. In three of the six villages (118 households) the full sequence was played. In addition, in two villages the most important dependent female of the household, usually the wife, was also included in the experiment up to the Rs.5 level (the

where U' and U'' are the first and second derivatives of the utility function. Other utility based measures of risk aversion are discussed in Binswanger (1978a) but S was the most convenient one.

Table 2. Sequence of Games and Hypothetical Questions

Game Number	Minimum Delay Since Last Event[a]	Game Level (Rs.)	Real or Hypothetical	Village[b]
1	First Day	0.50	Real	All
2	One day	0.50	Real	All
3	One day	0.50	Real	All
4	One day	0.50	Real	All
5	One day	0.50	Real	All
6	Two weeks	50.00	Hypothetical	Shirapur excluded
7	Same day	5.00	Real	All
	Same day	Hand out Rs.5.00 for next day game		
8	One day	50.00	Hypothetical	Shirapur excluded
9	Same day	5.00	Real	All
10	Same day	5.00	Hypothetical	All
11	Two Weeks	500.00	Hypothetical	Shirapur
12	Same day	50.00	Real	Kanzara
13	Same day	50.00	Hypothetical	Aurepalle only
14	Same day	50.00	Hypothetical	Kalman Kinkheda
15	Same day	5.00	Hypothetical	Dokur only
16	Two weeks	500.00	Hypothetical	Shirapur Kanzara
17	Same day	50.00	Hypothetical	Aurepalle only

[a] In many cases these minimum delays were exceeded by a few days.
[b] There are six villages, two each in three districts: Sholapur district—Shirapur and Kalman; Akola district—Kanzara and Kinkheda; Mahboobnagar district—Dokur and Aurepalli. Each village contains a panel of forty households and households heads were included in all villages. In Kinkheda and Dokur the most important dependent female in each household was also included in the experiment in addition to the head of household who, on occasion, was female.

dependent female sample). In five villages a nonrandom sample of the three "most progressive" farmers of the village was added (the progressive farmer sample). Progressive farmers are early adopters of new techniques. They were identified by the resident investigators on the basis of the investigator's knowledge of the villages. For all games except at the Rs.0.50 level, respondents' choices were ascertained by a first investigator and verified with the respondent by a second investigator. In about 250 games, including all the 50-rupee games, the author was the second investigator. In only two cases did the respondent change his mind. It was clear that the respondents enjoyed the game. No attempt was made to isolate the respondents from their peers except for the second verification. Agricultural decisions are also observable in the village context and their outcomes are known to all.

Reliability Tests

The first test was concerned with whether behavior with gift money differs from behavior with own money. (A fuller account of these tests is given in Binswanger 1978c.) To pretest the method, ten individuals were at one stage asked to play the game with their own money, and nine out of ten chose the same alternative as in the immediately preceding game, while one respondent became more risk-averse. With the household heads of the full sample a different test was carried out: one day prior to game 9, Rs.5 were given to the respondents and they had the choice not to come to play game 9 (such a choice was interpreted as the riskless choice O). If they chose to play game 9, they had to pay back any losses relative to the Rs.5 of that bet. If after gift money was in their possession for one day the respondents considered it their "own," comparison of the risk aversion distribution of game 7 and game 9 is a test of differences in behavior with gift and one's own money. A chi-square test of differences between games 7 and 9 in the distribution of choices over the alternatives was not significant at 0.05 level.

The second test concerned the usability of answers to hypothetical games included in the sequence. It was hoped that after playing the full sequence up to the Rs.50 level, individuals would acquire the introspective ability to tell how they would play at the Rs.500 level. One could then use the hypothetical answers as if they were real choices. Hypothetical games 6, 8, and 13 at the Rs.50 level were introduced in two villages (Aurepalle and Kanzara) for comparison with the real 50-rupee game. Chi-square tests at the 0.5 level showed that, before playing the 50-rupee game, people believed that they would act either more aversely or less aversely to risk than they actually did in the real game 12, i.e., the risk-aversion distribution was far more dispersed in the early hypothetical answers than in the real game. However, once the 50-rupee game was played, there was no statistically significant difference between the real choices in game 12 and the hypothetical answers to games 13 or 17. The data also indicate that the ability of respondents to predict their actual behavior in a hypothetical question increases as the game sequence proceeds, even before the 50-rupee game is played. Therefore, from this point on, the hypothetical 500-rupee game number 16 will be interpreted as if it really had been played, albeit with caution.

The third test was to investigate whether individuals, when confronted with a game such as in table 1, had an automatic tendency toward alternatives in the center of the distribution. Table 1 contains two risk inefficient alternatives D and D^*, which are derived from C and F, respectively, and have the same means but higher variance. No risk-averse individual should choose these alternatives, and they were introduced precisely to test whether people could detect stochastic dominance in this simple context.

Note that in a game structure containing D but not D^*, alternative C is the most central alternative and, under the "central tendency hypothesis," should be the most preferred one. On the other hand, if D is deleted from table 1, alternative D^* becomes the most central one. In three villages half the respondents were given the game structure containing the alternative D, while the other half were given the game structure containing D^*. It was found that for both games 9 and 12, the frequency distributions associated with the two game structures could not be distinguished statistically.

There were three potential learning effects in the experiment. The first one concerned the ability to know risk preferences when the participant is faced with a hypothetical question without making an actual decision, which was discussed above. A second potential learning

effect was revisions of personal probabilities of heads and tails in coin tosses, which will be discussed later. A third learning effect concerned the rules of the games. How many games did one have to play till one was sufficiently familiar with the rules? A chi-square test of the differences in risk aversion distribution was performed between the successive 0.5-rupee game; these tests were not significant, although there was a trend toward less risk aversion as the games proceeded. Respondents thus appeared to familiarize themselves quickly with the rules.

When using the Dillon and Scandizzo interview method (to be discussed in a later section of this paper), two investigators were identified who tended to elicit substantially different certainty equivalents while interviewing the same respondents. These investigators were assigned to two different subsamples—forty respondents each, twenty in each of two villages—for the entire game sequence. No statistically significant differences could be found between the risk-aversion distributions of the two subsamples and investigator bias appeared to be less of a problem using the game method than with interview methods.

The Main Experimental Results

The risk-aversion distributions corresponding to different game levels are given in table 3, in the first panel for those villages where the game was played up to the 50-rupee level (with a hypothetical answer at the 500-rupee level) and in the second panel for all the households, including those where the game was played only up to the 5-rupee level. Observe that at low levels of the game the distribution was fairly evenly spread across the four classes of intermediate risk aversion to risk neutrality. As the game level rose, the distribution shifted to the right and became more peaked, i.e., risk aversion increased.

Consider the slight-to-neutral and neutral-

Table 3. The Effect of Payoff Size on Distribution of Risk Aversion

Payoff Level and Game Number	Extreme	Severe	Intermediate	Moderate	Slight-to Neutral	Neutral to Negative	Inefficient	Sample Size
	Household Heads: Shirapur, Kanzara, Aurepalle							
A 0.50 No. 2	1.7	5.9	28.5	20.2	15.1	18.5	10.1	119

Distributions tested	χ^2	*df*	χ^2 0.05
A vs. *C* vs. *D* vs. *E*	85.68	18	28.87
C vs. *D* vs. *E*	48.49	12	21.03
A vs. *C*	11.91	6	12.59
B vs. *D*	44.22	6	12.59
D vs. *E*	23.46	6	12.59
A vs. *B*	13.17	6	12.59
F vs. *G*	16.30	6	12.59
G vs. *H*	50.02	6	12.59

to-preferred classes: at the Rs.0.50 level, the percentage in each of these classes is around 15 to 20, and it falls monotonically to near zero as the payoff level rises to Rs.500. In the moderate risk-aversion class, we initially find around 20% of the individuals. This percentage first rises at the Rs.5 and Rs.50 levels because people enter this class when leaving the lower risk-aversion classes. But between the Rs.50 and Rs.500 level, the number of entrants from lower risk aversion is lower than the number of individuals who become more risk-averse and the frequency in this class declines. The intermediate risk-aversion class starts out with 28.5% of individuals in game 2 at the Rs.0.50 level. As that game is repeated people prefer to play at higher stakes. But as the payoff level rises again, more people enter this class from the lower risk-aversion classes and at the Rs.500 level more than 50% of individuals are concentrated in this single class. The 500-rupee game corresponded to payoffs in the order of substantial fertilizer investments for these households, and many were too poor to undertake them. For some households it even exceeded net wealth.

The extreme and severe risk-aversion classes together contained less than 10% of the individuals for all levels except the Rs.500 level, in which the percentage rose to 15. There appears to be an upper barrier to risk aversion that is exceeded only very slowly at high stakes.

In any given game, around 10% of individuals chose one of the inefficient alternatives. This is clearly lower than the percentage of individuals who would choose it on a random basis. Consider game 12. Inefficient alternatives exist between the intermediate and moderate and the moderate and slight-to-neutral alternatives. These three classes and the inefficient ones contain 90.7% of individuals. If people fell into the two inefficient and three efficient classes at random, the two inefficient classes would contain at the very least one-fifth of the 90.7% observations, i.e., 18.1%, but the actual percentage was 9.3.

Who chooses inefficiently varies much across games. Two hundred and eighty seven individuals played all the games from 1 to 9. Of those, ninety-four (or 33%) chose one of the inefficient alternatives at least once, i.e., they did not recognize that they were stochastically dominated, or did not care about it at least once.

The evidence can thus be summarized as follows. For individuals with initially low risk aversion, it tends to rise fairly rapidly as game levels start to rise beyond trivial levels. For individuals who initially have intermediate to moderate levels of risk aversion, the level increases slowly or remains fairly constant as game levels rise. As can be seen from the chi-square tests (bottom of table 3), these trends are statistically significant and evident in both the reduced sample and the full sample of households.

Interpreted in the utility framework, the evidence suggests that all but one of 118 individuals have nonlinear, risk-averse utility functions, which exhibit increasing partial risk aversion.[4] It has been shown elsewhere (Binswanger 1978c) that the results also imply decreasing absolute risk aversion. Relative risk aversion first decreases and then increases.

Interviews versus Gambling Experiments

The most immediately comparable study to the present one (and the one which initially inspired it) is by Dillon and Scandizzo for a semi-arid tropical region of Brazil. It had a sample size of 103 farmers. Prior to the gambling experiment, the author executed a similar interview-based survey in the Indian SAT villages. In this section the author describes the problems encountered with the Dillon-Scandizzo method and then compares the results of the two surveys with each other as well as with the experimental results.

Dillon and Scandizzo describe their method as follows: "The farmer's risk attitudes were appraised via their choices between hypothetical but realistic farm alternatives involving risky versus sure outcomes. These questions

[4] To obtain unique measures of partial risk aversion associated with the indifference points between two alternatives, a constant partial risk-aversion function (CPR) of the form $U = (1 - S)M^{1-S}$ was used. Given the evidence of increasing partial risk aversion one might object that an increasing partial risk-aversion function (ICPRA) should have been used (Binswanger 1978b). However, the partial risk-aversion coefficient for any indifference point will then not be unique but will depend on the rate at which partial risk-aversion increases, i.e., on the choice paths across the game scale. Therefore, partial risk-aversion coefficients were computed for each indifference point at each game scale and for each feasible choice path given a smooth ICPRA utility function. Because income varies more across game scales than within each game scale, S values associated with these ICPRA differed by less than 2% from those associated with the CPR functions, except for the indifference point between alternative O and A, where the largest difference was 15%. Because few respondents chose alternative O to A, the results of this paper would not be substantially affected by using S values from an ICPRA function.

form the basis of our empirical analysis and were geared to finding the certainty equivalents of risky prospects involving stated probabilities. Two types of risky prospects were used, yielding two subsets of responses for each group of farmers. The first type involved only payoffs above household subsistence requirements. In these, while the level of total income was at risk, subsistence was assured. The second type of risky prospect included the possibility of not producing enough to meet subsistence requirements. Both types of risky prospect involved only two possible outcomes whose probabilities were specified as invariant frequencies" (Dillon and Scandizzo, p. 427). These frequencies were 0.75 ("3 years out of 4") for the "good" outcome and 0.25 ("1 year out of 4") for the "bad" outcome.

In the Indian study the "good" outcome and the "bad" outcome of the uncertain prospect are fixed so that the expected value of the uncertain prospect was one-half of subsistence income and twice the subsistence income, respectively. Subsistence income previously had been established for each household individually by asking householders, item by item, their minimum annual requirement of all food and clothing. Subsistence income ranged from Rs.462 to Rs.14,117. The certainty equivalent of the prospect was then found by varying the certain income until indifference with the uncertain prospect was attained.

When analyzing the results of the Indian survey, several problems and inconsistencies were encountered. The most serious was that in two neighboring villages, Shirapur and Kalman, the distributions of risk-aversion coefficients differed sharply. For table 4, the elicited survey results were converted into partial risk-aversion coefficients using a constant partial risk-aversion function (see footnote 4) and grouped into the same classes as those of the experimental study, except that the intermediate and moderate classes were pooled. The second and third line of table 4 (Shirapur First and Kalman First) compare the results for the first survey carried out by investigators A and B, respectively. Shirapur appears to be more risk-averse and the difference is statistically significant.

The villages were then resurveyed, switching investigators, and the results are given in the line 1 and line 4 of table 4. Comparison of line 1 with line 2 and line 3 with line 4 clearly shows that in each village investigator B classifies respondents as more risk-averse than investigator A, and these differences are statistically significant. This cannot be caused by the time lag of more than a month between interviews because the time sequence of investigators was reversed between the villages. Thus, the interview technique is subject to severe interviewer bias. Resurveys also were carried out in other villages. By analyzing all resurvey results, it was found that in more than 20% of the cases individuals were reclassified radically between extreme risk aversion and neutrality or negative and positive risk aversion. In the game results, such radical reclassification in successive games at the same level is rare (Binswanger 1978a).

Table 5, lines A and B, show the distributions for the 50- and 500-rupee games, while lines C and D show the India interview results

Table 4. Survey Results in Shirapur and Kalman

Risk Aversion Distributions Obtained by Different Investigators in Two Villages[a]

Village and Survey	Investigator	Survey or Resurvey	Risk-Aversion Class: Extreme	Severe	Intermediate or Moderate	Slight or Neutral	Negative	Number of Observations
Shirapur (second)	A	Resurvey	10	9	4	5	5	33
Shirapur (first)	B	Survey	20	10	3	0	0	33
Kalman (first)	A	Survey	4	5	5	11	4	29
Kalman (second)	B	Resurvey	11	12	1	2	3	29

Relevant chi-square tests, all significant at better than 0.01 level.
[a] In absolute numbers.

Table 5. Comparison of Interview-Based and Experimentally Based Distribution of Risk Aversion

	Extreme	Severe	Intermediate or Moderate	Slight or Neutral	Negative	Inefficient	No. of Observations
			India				
A. Game no. 12; Rs. 50	2.5	5.1	74.6	6.8	1.7	9.3	118
B. Game no. 16; Rs. 500	2.5	8.2	85.9	0	0.9	2.5	118
C. Interview Subsistence-at-risk[a]	27.0	34.3	18.0	6.3	14.4	n. appl.	222
D. Interview Subsistence-assured[a]	18.2	43.6	15.5	9.1	13.6	n. appl.	220
			Dillon and Scandizzo's Interview Based Results from Brazil[b]				
E. Subsistence-at-risk[a]	26.2	57.3		0	16.5	n. appl.	103
F. Subsistence-assured[a]	32.0	32.1		8.7	27.2	n. appl.	103

(A) vs. (C) or (A) vs. (D) Chi-square > 95; $\chi^2(4,0.05) = 9.49$

Note: Comparisons are in percentage of number of observations.

[a] Subsistence-at-risk and subsistence-assured refer to two different payoff levels. In the first, the "bad" outcome would result in the farmer not being able to meet his subsistence income while in the second case the bad year outcome would exceed the level.

[b] Computed from tables 2, 3, and 4 by combining the data for sharecroppers and small farmers. The 103 respondents do not include 15 respondents who were not willing to answer the questions or whose answers were internally inconsistent, as judged by the interviewers. Similarly, the 222 farmers in the Indian interview studies excludes roughly 10 respondents on similar grounds.

for the Rs.50 and Rs.500 levels, which come closest to the usually higher payoff levels used in the interviews. The interview results classify more than 50% of individuals as extremely or severely risk-averse and close to 15% as neutral or negative. This is in sharp contrast to the game results for the same households. Dillon and Scandizzo give explicit data on the slight-to-neutral and negative classes of risk aversion, but not on the "extreme" classification. In table 5, lines E and F show individuals in the extreme class who opted for the highest possible certainty equivalent in their study. Interestingly, the interview results for Brazil are somewhat similar to those for India, identifying substantial proportions of individuals with extreme and negative risk aversion. Other interview-based studies also appear to find higher dispersion of risk-aversion coefficients than those identified here (O'Mara, Kennedy).

Given the clearly documented interviewer biases and high instability of interview results relative to game results, one is tempted to dismiss the interview studies as unreliable and potentially misleading. Some caution may be necessary, however, because the interview methods differ in significant ways from the game method. First, the interviews about an income stream from assets or occupations, while the game results are about one-period gambles. In the light of footnote 1, it is conceivable that the two methods measure different concepts. Second, the distribution of outcomes is skewed in the interviews but symmetric in the games.

On the other hand, one should not underestimate the problems associated with any interview method. In the third section, it was shown that at the early stages of the game sequence the respondents' replies to hypothetical questions at the Rs.50 level differed significantly from the real choices and implied much more dispersed risk-aversion distributions. Furthermore, the distributions also were more widely spread at the very low game level of one-half-rupee than at high game levels. Interview methods are inevitably faced with the problem that individuals may not be able to reveal their attitudes towards decisions they have never taken or seriously contemplated. And even if the payoffs discussed in hypothetical questions are high, there are no real payoffs or penalties associated with revealing a preference which may or may not correspond to how one would act when faced with real choices, i.e., true payoffs are even lower than those in the one-half-rupee game.

Correlation of Risk Aversion with Personal Characteristics

Empirically, virtually nothing is known about how personal characteristics of individuals are correlated with risk aversion. This section is concerned with correlations of risk aversion

with personal characteristics regardless of the causal nature of the relationship and therefore can look at personal characteristics that may be determined jointly with risk aversion. In order to use multiple regression, a number of scaling decisions have to be made to assign risk-aversion "numbers" to the discreet classes. At the simplest level, numbers zero to five are given to the choices O to F, and they are used as regressors. Other scales are based on the tradeoff Z and on partial risk aversion S. A substantial number of regressions were performed using these three variables and functional transformations thereof. These variables and transformations had little impact on the sign patterns of the coefficients, but the regressions using ln S had, on an average, the highest $\bar{R}^2$, and are therefore retained. Furthermore, the full data set was divided into subsets of different villages and for males and females separately. F-tests indicated that these sets could be combined for all games, i.e., coefficients did not differ significantly across data subsets. The regressions in table 6, however, exclude the dependent females data because their observations are not independent of those of the household heads. Signs and significant levels of coefficients were fairly

robust in these experiments with functional forms, and, where that was not the case, it will be signalled in the text.[5]

For the partial risk-aversion coefficient S, the following scaling decisions are involved. The choices of an alternative indicate a range only for S. The geometric mean of the end points is assigned as the measure of S.[6] In the case of alternative F, a value of zero is given to S although it could be negative. Given the result that practically no one prefers risk at high game levels, a value of zero is not unreasonable.[7] For alternative O, the upper bound for S is equal to infinity, while its lower bound is 7.50. Because in the experiment very few individuals chose alternative O, it is reasonable to assume that their partial risk aversion should not exceed 7.5 by very much, and this value was increased by 12% to give a value of 8.4. It is easy to find fault with any of these scaling decisions, and they can be defended only by the apparent insensitivity of results to alternative scalings.

In table 6, the coefficients of the variables with ln S are given. To judge the magnitude of the effects implied, table 7 computes a predicted S for the Rs..5 and Rs.50 levels and compares it with the geometric average S in the sample (first line, underlined values). The predicted S is computed as follows: add to the average S the shift implied by the regression coefficient for a move from the average value of the independent variable to the largest value observed in the sample.[8] Table 7 also shows which choice would be implied by the new value of S.

Thirteen variables are included in the regressions, apart from the village dummies, which are included to take account of effects on risk aversion of such variables as agroclimatic differences, and others.

In the regressions, wealth is measured by gross sales value of physical assets. It would have been better to use net worth rather than gross wealth. However, the data on borrowings and lendings are scanty, but imply that at higher wealth levels borrowings were a small fraction of gross wealth. In these households, on an average, 69% of physical wealth was held in the form of land. The weakness of the relationship between physical assets and risk aversion is surprising, given the fairly strong effect of the game size. Across games the sign of the coefficient is consistently negative, but not always statistically significant. The (statistically not significant) coefficient of −0.0041 in the 5-rupee game 7 implies that a shift from average wealth to the largest wealth observed in the sample is just sufficient to bring an individual from choice C to risk neutrality. It would not be sufficient to move an individual

[5] A decision also had to be taken as to what to do with the "inefficient choices" D and D^*. Leaving out everyone who chose an inefficient alternative at least once would have drastically cut the sample. A comparison of regression where they were left out with regressions where choice D was treated as its neighboring choice B and choice D^* as choice C revealed no differences in sign patterns and coefficient sizes but reduced standard errors. The results reported thus include the inefficient choices.

[6] For alternative E at one of the endpoints, $S = 0$ and the geometric mean of both endpoints would be zero. Therefore, the arithmetic mean was chosen in this case.

[7] For logarithmic transformations, a value of zero is inadmissible. It was therefore rather arbitrarily set at 0.0007.

who initially was indifferent between A and B to choose alternative E.

For the crucial 50-rupee game, the coefficient is usually of the unexpected sign (positive, close to zero, and not significant). Contrary to expectations, wealth has little impact on individuals' behavior at game levels that are commensurate with monthly wage rates or small agricultural investments.

Another form of wealth is human wealth and "schooling" is a proxy variable for it. Average schooling in the sample is two years, but the maximum is sixteen years, i.e., the distribution is highly skewed. At low game levels this variable had little influence on risk aversion, but at the Rs.5 level and above, it generally reduced the level of risk aversion and was often statistically significant, although not generally so in the regressions using log S. But again, the impact of schooling was not massive. In the 5-rupee game, the coefficient size of -0.0432 implies that an individual who has fourteen years of schooling rather than one would fall into the slight-to-neutral class rather than the intermediate class. At the Rs.50 level, the same difference is not sufficient to shift the individual's risk aversion by an entire class interval.

Two variables that are correlated with schooling are the amount of income received in the form of salary (i.e., from a secure job) and a dummy variable for progressive farmers. Salary employment, with some exceptions, is restricted to individuals with schooling, and totally illiterate individuals have no access to it (58% of the household head sample had no schooling). Progressive farmers are those whom the resident investigators designated as the early adopters of new techniques (five in each village). Schooling is again correlated with this variable and can be expected to contribute to it. Note that in regressions where these two variables were suppressed, schooling did become statistically significant.

"Salary employment" by itself tended to decrease risk aversion, the sign being fairly consistently negative, although it was not statistically significant at the Rs.50 level. Similarly, the progressive farmer dummy had a fairly consistent negative sign, but at the high game levels its coefficient was so small that it was not significant.

Economists would not usually expect that past experience with a random process, which is as transparent as flipping a coin, would have a strong impact on a person's next choice over alternatives defined on it. Psychologists, on the other hand, would not find this surprising, and the present experiment suggests a strong impact of prior luck. Past experience, or luck, is defined as $\sum_i X_i$, where i is the game number 1, 2, 3, 4, 5, 7, 9, and 12, and X takes a value of 1 when the person wins, -1 when he loses, and zero when he neither wins nor loses (alternative O). The coefficient is consistently negative and always statistically significant. Note also that its size tends to decline as the game level rises, i.e., its impact is weaker the higher the stakes. Nevertheless, at the Rs.5 level (after seven games), a person who had consistently won (luck = +7) would have a greater tendency to shift from playing alternative C to playing alternative E than a person who had had an equal number of gains and losses. Finally, past experience does not wear off rapidly. The answers to the 500-rupee game were collected two or more weeks after the last game had actually been played.

Whether the influencing of this variable reflects revision of personal probabilities, or learning about them, or some other effects cannot be answered by this experiment.[9] Because "luck" in this experiment is a random variable uncorrelated among individuals it has impact on individual choices but not on the risk-aversion distributions. However, farmers in a given area face highly correlated weather outcomes. That past experience should have such an impact on risk aversion suggests that farmers would be more reluctant to invest after a series of droughts (even if they had the same wealth levels as before the drought) than they normally would on account of their own average risk aversion.

Age has a positive sign in games up to the Rs.5 level but a negative sign at the Rs.50 and Rs.500 level. At the Rs.50 level it is statistically significant but not at the Rs.500 level. Is it possible that young people are more willing to engage in risky games at low stakes, whereas older people having dealt much more in risky economic games at high stakes might be more willing to take risks at high levels? But at the Rs.50 level, the quantitative impact

[9] Psychologists working experimentally in the area have found that individuals exhibit preferences for heads or tails in coin tosses. Because the winning sign of the coin was charged for each game level, such preference cannot account for the observations on the luck variable. But it is possible that the preferences for one side of the coin seen in earlier experimental work might be caused by a person having had a winning or losing streak on one side of the coin.

of even thirty-eight years of age difference is not sufficient to shift an individual's choice by an entire class interval.

The "women" dummy variable exhibits inconsistent coefficient signs. At high game levels it does not appear to affect behavior at all. Clearly, there is little support for the hypothesis that women are less willing to take risks than men, once adjustment is made for variables such as schooling. In tabular analysis it was noted that, on an average, women were slightly more risk-averse than men (means not significantly different). At best, one can explain this by the fact that, in the environment studied, women did not have equal access to education as men. Not a single woman in the sample ever attended school.

The variable "working age adults" approximates the proportion of productive individuals in a household: it varies on the unit interval, i.e., it is the weighted number of adults between the ages of fifteen and fifty-nine years divided by the weighted sum of family members.[10] The lower this ratio, the higher the proportion of individuals whom the working age adults have to support. One would thus expect the variable to have a negative sign by saying that those with few dependents can afford to take more risk. This hypothesis is not supported by the data. The coefficient shifts in sign and is hardly ever significant. At higher game levels it is consistently positive, i.e., of unexpected sign.

A portion of the new literature on tenancy assumes that share tenancy is used to spread the riskiness of farming (Bardhan and Srinivasan). The reasoning is not based on differential risk aversion between landlords and tenants, but it would be strengthened considerably if tenants were generally more risk-averse than landlords. The "land rented" variable measures the net area leased by a household regardless of the form of contract. It is negative for landlords and positive for tenants. At low game levels there was some indication that tenants were less risk-averse than landlords, not vice-versa. At high game levels there appeared to be no difference.

"Net transfers received" measures the net amount of income transfers received from relatives and other sources between 1 July 1975 and 30 June 1976. It was negative for those who sent transfers. It usually had a negative sign, which is consistent with the hypothesis that the possibility to rely on income transfers reduces risk aversion because it insures against adversity. It is not a good measure of "insurance" via transfer mechanisms because it measures what has actually been received rather than what can potentially be received, yet it is the best that can be done at this stage.

The individuals who liked to gamble (by buying lottery tickets or by playing cards, with and without money) were identified. Less than 5% of individuals fell in this category, and the variable leads to contradictory results.

Table 5 shows that coefficient sizes were generally smaller at the Rs.50 level than at the Rs.5 level. This is not surprising because the distribution of risk-aversion coefficients is more concentrated at the Rs.50 level than at the Rs.5 level.

Gambling Results and Farming Decisions

As measured by the gambling experiment, the main conclusions of this study are as follows: (*a*) At very low payoff levels, risk aversion is fairly widely distributed from intermediate levels to risk neutrality or preference. (*b*) At payoff levels in the neighborhood of monthly labor incomes or small agricultural investments, risk aversion is highly concentrated at the intermediate and moderate levels, and risk neutrality virtually disappears. (*c*) At these high payoff levels, wealth does not appear to influence risk aversion significantly, although at low game levels such an effect appears to exist.

If these results can be extrapolated to farming decisions, they suggest that differences in investment behavior observed among farmers facing similar technologies and risks cannot be explained primarily by differences in their attitudes but would have to be explained by differences in their constraint sets, such as access to credit, marketing, extension, etc. It is not the innate or acquired tastes that hold the poor back but external constraints. Policy in support of poor farmers and landless laborers will have to be geared toward removing these constraints rather than being risk-specific.

[*Received May 1979; revision accepted January 1980.*]

[10] In computing the ratio, adult males (above 15 years of age) were given a weight of 1; adult females, 0.8; and children, 0.5.

U.S. Agricultural Policy and Gasohol: A Policy Simulation

Ronald L. Meekhof, Wallace E. Tyner, and Forrest D. Holland

This research uses a stochastic simulation model to evaluate the implications of alternative gasohol programs for a large segment of the food and agricultural sector—corn and soybean producers, consumers, and taxpayers. The impacts on corn and soybean prices, production, acreage planted, carryover stocks, exports, and commodity program expenditures are presented. The research findings indicate that alcohol production levels below 2.0 billion gallons do not result in serious dislocations in the agricultural sector. As the level of alcohol production increases and more grain is required, corn prices rise significantly, stocks fall to extremely low levels, exports decline, and government expenditures increase greatly.

Key words: agricultural policy, alcohol, energy, gasohol, simulation.

Federal policy toward oil prior to 1973 was a patchwork of restrictive measures justified on the grounds that national security required a strong oil industry. The energy policies of the United States during this period have been characterized as "surplus policies" (Mitchell). An import quota restricted domestic production in order to support the price of domestic crude. These policies were operable because there was a worldwide surplus of oil. Since the Arab oil embargo of 1973, the thrust of the U.S. energy policy has been to "manage the shortage" and stimulate supply with an intricate system of price controls for crude oil and refined products together with programs for allocations and entitlement payments.

Agricultural policy has undergone a similar transition. The underlying supply and demand conditions have not, however, dictated a stringent shortage management policy approach. Reliance on price support and supply control programs to reduce chronic over-production have given way to increased reliance on managed grain reserve programs and measures to modify the impacts of competitive and unstable markets. With the impending shortage of liquid fuels, a new set of economic factors are invoked that may warrant further change in agricultural policy.

The utilization of grain for the production of gasohol—a blend of 10% alcohol produced from grain and 90% gasoline—has gained substantial interest among those concerned with agricultural and energy policy. Gasohol production is perceived as a means of utilizing agricultural land periodically withdrawn from production to increase domestic energy supplies.

Previous research on this issue concludes that gasohol production is not currently economically viable, given current relative factor and product prices and alcohol production technology (Tyner and Bottum). With alcohol distilled from grain costing considerably more than the current wholesale price of gasoline, a subsidy would be required to make alcohol competitive on a cost basis with gasoline. Alcohol is, however, competitive with synthetic fuels derived from coal and oil shale. The wholesale cost of all these fuels will be $1.20 per gallon or higher. Yet, within the current context of rapidly rising energy prices, periodic grain surplus, and acreage set-asides, the economic implications of policy alternatives that potentially could improve resource use in both the agricultural and energy production sectors need to be evaluated.

As might be expected for an issue with important implications for both agricultural and energy policy, several gasohol program alternatives have emerged in the legislative pro-

Purdue Agricultural Experiment Station Journal Paper No. 7662.

cess. The proposed gasohol programs generally provide (*a*) a subsidy for gasohol production, (*b*) measures to enhance the level of grain production, and (*c*) measures to assure a minimum supply of grain to distillers. Without reference to specific legislation, this paper examines an alternative agricultural program under the assumption that demand exists for grains used in gasohol production.

The analysis presented here compares a modified agricultural program designed to meet various levels of gasohol production with an extension of those programs currently in effect.[1] Under the modified program, the income and acreage set-aside programs are eliminated. Loan rates are increased to levels that would provide producers with about an equivalent production incentive and level of income protection as that provided by current commodity programs. Increased loan rates also are utilized as a means to increase inventories of the Commodity Credit Corporation, which assumes the additional marketing role of providing a minimum amount of grain to alcohol distillers. Four different levels of alcohol production are evaluated with respect to their impacts on prices, production, exports, carryover stocks, and government expenditures for corn and soybeans.[2]

Model Description

A stochastic simulation model was used to evaluate and compare the implications of the gasohol and extension of current commodity program alternatives on economic variables characterizing U.S. corn and soybean markets. *FEEDSIM*, a model of the U.S. corn and soybean markets, is comprised of annual production, demand, and government program components, and incorporates interaction in supply and demand for both commodities. Since *FEEDSIM* is documented in detail elsewhere (Holland and Meekhof), only those modifications that were necessary to address the gasohol program alternative are discussed here. Those modifications include incorporating (*a*) the commitment by the CCC to supply grain to alcohol distillers, (*b*) the subsidy needed to make alcohol production competitive, and (*c*) the impacts on soybean demand resulting from increased supplies of distillers dried grain.

The gasohol program analyzed here requires a corn supply commitment equivalent to that needed to produce 1.0, 2.0, 3.0, or 4.0 billion gallons of alcohol—385, 769, 1154, and 1538 million bushels per year of corn, respectively. The alternative levels of supply commitment are purchased and sold by the CCC. This modification is incorporated in the stocks component of the model by specifying that the CCC make available that amount of grain from either inventories accumulated through nonrecourse loan defaults or purchases from the market, which equal the difference between the levels of supply commitment and quantity defaulted. The CCC is charged the loan rate for grain withdrawn from inventories and the market price for grain purchased from the market.

The per bushel corn price used to calculate CCC revenues is that required to make gasohol competitive with gasoline—\$.75 in 1979.[3] This 1979 price is increased 10% annually in following years to reflect rising gasoline prices. The subsidy for gasohol production is equal to the difference between the average price the CCC is charged for the grain supply commitment and price for grain that makes gasohol production competitive.

The process of grain to alcohol conversion also results in the production of distillers dried grain—a protein source that substitutes for soybean meal at a rate of 2 to 1. Each bushel of grain used in gasohol production reduces domestic soybean demand by .19 bushels.[4]

[1] The original analysis included comparison of two alternative gasohol programs. The two gasohol program alternatives differ primarily in the manner in which producers are encouraged to increase production above export, domestic demand, and reserve needs to meet gasohol supply commitments. Complete results of both program alternatives are available from the authors in a paper entitled "U.S. Agricultural Policy and Gasohol: Simulation of Some Policy Alternatives."

[2] Two important issues are not covered in this analysis. First, increased row crop production would increase soil erosion. The associated loss in environmental quality has not been considered explicitly in this analysis. Clearly, however, any policy decisions would include this important factor. Second, net energy analysis is not included here because of space limitations. The general consensus is, however, that with current technology for new plants, alcohol production is a net producer of premium fuels even with increased fertilizer use.

[3] Seventy-five cents was the corn price required to make alcohol cost competitive with gasoline in April 1979. If petroleum prices rise faster than our assumed 10% per year, the break-even price would be higher and CCC subsidies lower than the results here indicate.

[4] Modifications incorporated in the model specify full utilization of the distillers grain as a protein substitute for soybean meal. While this is not likely, the modification was done in this manner to illustrate the most severe case. It is more likely that some of the distillers grain would be fed wet as corn substitute. To the extent that the corn substitution occurred, soybean demand would be diminished less than indicated in these results. The results shown here should be interpreted with this factor under consideration.

Current utilization levels indicate that the substitution possibility of distillers dried grain for soybean meal would cease to exist for alcohol production levels greater than 3.0 billion gallons because that amount of distillers grain would substitute for all currently fed soybean meal.

Program Alternatives

The analysis compares the gasohol program alternative and an extension of current commodity programs for the period 1979/80 through 1984/85. Assumptions are made with respect to the level of commodity program parameters for each alternative for individual years in that period.

The current program alternative (*CURRENT*) incorporates announced target prices, loan rates, set-aside levels, and reserve program parameters for 1978/79–79/80. Target prices in the remainder of the period are adjusted on the basis of the formula contained in the Food and Agriculture Act of 1977 and projected input costs. Loan rates, and corresponding farmer-held reserve parameters, are escalated on the basis of the trend in corn prices received by producers from 1960–76. Set-aside levels are calculated internally by the model. The specific values for the *CURRENT* program parameters are shown in table 1.

Other limitations of the model include the exclusion of acreage responses from other feed grains and other sources of adjustment that may, in the long run, ameliorate the increased demand levels, and stockholding by alcohol distillers to buffer severe supply and demand conditions.

Announced program parameters for 1978/79–79/80 also are specified for the gasohol program alternative, *GAS-I*, with the exception of the 1979/80 loan rate being raised to $2.10. The loan rate for 1980/81 is set at $2.20 and adjusted in subsequent periods by the target-price adjustment formula specified in the 1977 Act and projected input costs. Farmer-held reserve (*FHR*) program parameters reflect these adjusted loan rates. Both target prices and acreage set-aside programs are eliminated for the 1980/81–84/85 period. One-half of the supply commitment levels specified above would be utilized in 1980/81 with full supply commitment levels being in effect in remaining years. Specific values for program parameters under *GAS-I* are shown in table 1.

Empirical Results

The following discussion emphasizes empirical results for supply commitment levels of 769 and 1538 million bushels for the *GAS-I* alternative (corresponding to 2 and 4 billion gallons of alcohol). These levels are representative of, and are referred to in the text, as low and high levels of alcohol production.[5]

Acreage Planted and Production

In the later years of the period considered, corn acreage planted for *GAS-I* is substantially

[5] Our current gasoline consumption is about 110 billion gallons per year so these levels are about 2% and 4% of total gasoline consumption. While these are small amounts relative to our total gasoline consumption, they are quite large relative to the magnitude of recent supply disruptions.

[a] Under the *GAS-I* program, the CCC only releases stocks to meet gasohol supply commitments, thus altering currently employed provisions of releasing stocks at 150% of the loan rate.

higher than those indicated under the *CURRENT* alternative. The difference of 7 to 10 million acres is caused largely by the acreage response to higher corn prices relative to soybeans and the elimination of acreage set-asides. With corn yields averaging about 3.5 bushels per acre less under the *GAS-I* levels of production, the difference in production is less than that indicated by acreage differences. The average difference in production between *GAS-I* and the *CURRENT* alternative is 250 million bushels for both the low and high cases.

Figure 1 indicates no substantial differences between corn acreage planted under *GAS-I* for high or low levels of alcohol production. Corn acreage planted increases substantially with introduction of the gasohol programs and holds steady between 86 and 87 million acres in later years. Corn acreage for *CURRENT* averages 80 million acres for 1980/81–84/85 due to acreage set-asides.

Soybean acres show steady increases through most of the period of analysis under both the *CURRENT* and *GAS-I* alternatives (figure 2). Low levels of alcohol production reduce soybean acreage by, at most, 1.5 million acres, while at high levels of alcohol production the reduction is no larger than 1.9 million acres. The impacts on soybean acreage are explained largely by factors on both the supply and demand sides. Soybean demand is

Figure 2. Acres planted of soybeans

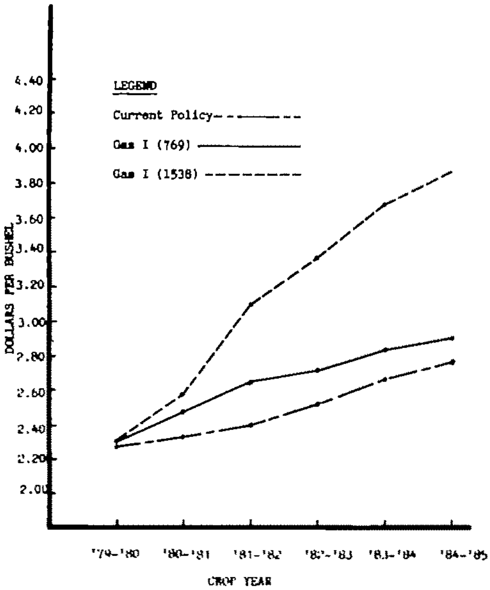
reduced because of the substitution of distillers dried grain for soybean meal. On the supply side, the relatively higher corn prices under the *GAS-I* alternative induce planting of more corn acreage and less soybean acreage.

Total corn and soybean acreage increase under the *GAS-I* alternative. Total acreage for both commodities averaged 153.7 million acres for *CURRENT* and 159.2 for the 2.0 billion gallon level under *GAS-I*. Total acreage did not vary substantially between high and low alcohol production levels for the *GAS-I* alternative. Over the last three years of the period of analysis, acreage planted for both commodities stabilized at levels about 8 million acres greater than *CURRENT* under *GAS-I*.

Prices

Figure 3 shows that corn prices under *GAS-I* are higher than with *CURRENT*, which average $2.53 per bushel over 1980/81–84/85. Corn prices for high levels of gasohol production are substantially higher, while corn prices at the 2 billion gallon alcohol production level average $.17 higher for *GAS-I* over the same period. The difference in prices between *CURRENT* and the 1.0 billion gallon level were negligible.

The stability of corn prices, as measured by the coefficient of variation, under low levels of alcohol production for *GAS-I* does not sig-



Legend: –·– *CURRENT* Program;
····· *GASOHOL-I* (Corn 769) Program;
--- *GASOHOL-I* (Corn 1538) Program

Figure 3. Corn prices

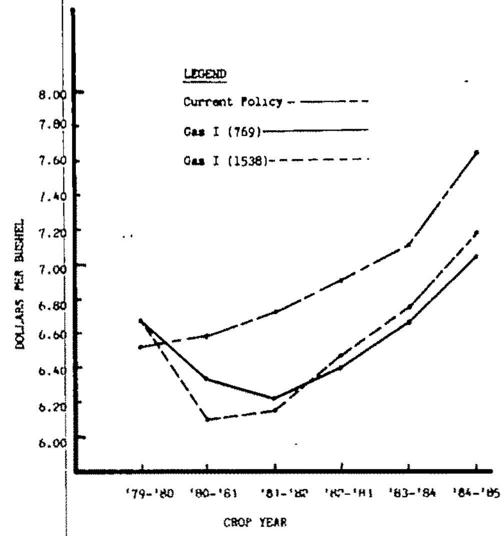
nificantly differ from *CURRENT* levels. However, the coefficient of variation for high levels of production under *GAS-I* increased by 66%. Soybean prices were not destabilized under the *GAS-I* program.

Soybean prices with the *CURRENT* program alternative average $7.00 per bushel from 1980/81 to 1984/85. High and low alcohol production levels under *GAS-I* resulted in average soybean prices of $6.52. The difference in soybean prices between *GAS-I* and *CURRENT*, which are shown in figure 4, was lower at the end of the period of analysis.

Exports

Figure 5 indicates that corn exports under low levels of gasohol production do not differ substantially from those with the *CURRENT* alternative, while for high levels of gasohol production, corn exports decrease by 200–300 million bushels in the middle of the period of analysis. The rebound in corn exports in the later years reflects the relative increase in soybean prices that occurred.

Evaluated at season average prices, the value of corn exports under *CURRENT* average $5.2 billion annually for 1980/81–84/85. At high levels of alcohol production, annual corn export values approach $6.0 billion. For high levels, however, instability in corn export



Legend: –·– *CURRENT* Program;
····· *GASOHOL-I* (Corn 769) Program;
--- *GASOHOL-I* (Corn 1538) Program

Figure 4. Soybean prices

quantities increases by 30%–40% under *GAS-I* for later years in the analysis.

The decrease in domestic soybean demand due to the substitution of distillers dried grain is partially balanced by increased exports as is shown in figure 6.

Corn Carryout Stocks

As is shown in figure 7, corn carryout stocks are lower with *GAS-I* than those under *CUR-*

Figure 6. Soybean exports

RENT alternative. The results also indicate that the reduction in stocks varies directly with the alcohol production level. At low levels of alcohol production the level of private stocks—the primary cushion for supply and demand shocks—are not significantly reduced. For the period 1980/81–84/85, private stock levels hold steady at about 1.1 billion bushels for *CURRENT* and *GAS-I* alternatives at the 2.0 billion gallon alcohol production level. For production levels of 3.0 and 4.0 billion gallons, private carryout stocks average about 900 million bushels and also trend downward to about 700 million bushels in 1984/85. At the 4.0 billion gallon level, average annual farmer-held reserve stocks are reduced to about 200 million bushels for *GAS-I*.

For alcohol production levels greater than 2.0 billion gallons, CCC carryout stocks are negligible. The frequency of CCC market purchases averaged 85% for *GAS-I* at the 4.0 billion gallon level. The trend in the frequency of CCC intervention in the market to meet alcohol production needs increased through time at high production levels.

Figure 7. Carryout stocks of corn

Government Expenditures

Government expenditures for CCC operations, income deficiency payments, acreage diversion payments, and FHR storage payment with the *GAS-I* alternative were generally greater than those for *CURRENT* at high alcohol production levels. For the 1.0 and 2.0 billion gallon alcohol production level, government expenditures were about the same for *GAS-I* and *CURRENT*. As is shown on figure 8, the level of government expenditure is sub-

stantially higher for high levels of alcohol production than for *CURRENT*.

Summary and Conclusions

The analysis provides a comparison between a policy alternative for various levels of alcohol production and an extension of current commodity programs. In general, it can be concluded that high levels of alcohol production result in outcomes that are probably not acceptable in the current food and agricultural policy context. From 1980/81 to 1984/85, season average corn prices increase from $2.53 under the *CURRENT* program to $3.32 for the 4.0 billion gallon alcohol production level. The annual instability in corn prices nearly doubles in some years at this level. Both results conflict with the interests of domestic and foreign consumers of U.S. corn and also with U.S. market stabilization objectives.

Private corn carryout stocks, the primary means to moderate supply and demand shocks are reduced by approximately 30% with the 4.0 billion gallon alcohol production level. Total stocks which include private and CCC stocks, are reduced by approximately 55%. While the implications for the ability to moderate either drastic supply reduction or demand increases is obvious, stock reductions to these levels may also impose constraints on meeting food security objectives.

At the 4.0 billion gallon alcohol production level, corn exports decrease by an average of 273 million bushels annually in 1980/81–84/85. Soybean exports increase by an average of 115 million bushels for this period. While corn export earnings increase by $.7 billion and soybean export earnings by $.3 billion at the 4.0 billion gallon level, the instability in corn export earnings increases by 35% in the later years of the period evaluated.

At the 4.0 billion gallon alcohol production level, government expenditures increase by an annual average of $1.3 billion for 1980/81–84/85—almost twice the average government expenditures for the *CURRENT* program for the same period.

At the 1.0 or 2.0 billion gallon alcohol production level, the results were quite different. Table 2 displays average values for 1980/81–84/85 for *CURRENT* and 1.0 and 2.0 billion gallon levels for *GAS-I*. Comparison of season average corn prices indicates little or no impact at 1.0 billion gallons of alcohol production. For 2.0 billion gallons, however, a $.17 per bushel increase is observed for *GAS-I*. The level of corn price instability is not affected. Soybean prices decrease significantly under these levels for *GAS-I*. Over the five-year period, planted acreage of corn increases by about 6 million acres under *GAS-I*. The difference in crop yields for higher acreage levels influence production levels.

Exports of corn do not differ significantly from *CURRENT* levels, while some strengthening is observed in soybean exports under the *GAS-I* alternative. The stability of corn exports is not affected at these levels. Total corn carryout stocks, while reduced from *CURRENT* levels, remain at sufficient levels to meet unexpected supply reductions or demand increases.

The value of corn production plus deficiency payments for corn producers in-

Table 2. Average Results at Low Levels of Alcohol Production—1980/81–84/85

Item	Units	*CURRENT* Program	*GAS-I* 1 Billion Gallon	*GAS-I* 2 Billion Gallon
Corn prices	$/Bu.	2.53	2.56	2.70
Soybean prices	$/Bu.	7.00	6.66	6.52
Corn acreage	Mil. Acres	80.4	86.5	86.7
Soybean acreage	Mil. Acres	73.3	73.4	72.6
Corn production	Mil. Bu.	7250	7569	7588
Soybean production	Mil. Bu.	2188	2192	2170
Corn exports	Mil. Bu.	2056	2115	1957
Soybean exports	Mil. Bu.	932	975	1005
Corn carryout	Mil. Bu.	1960	2146	1554
Value of corn production and deficiency payments	Bil. $	18.6	19.3	20.4
Value of soybean production	Mil. $	15.0	14.4	13.9
Government expenditures	Mil. $	1626	1635	1586

crease by $1.8 billion for *GAS-I* at the 2.0 billion gallon level. At the 1.0 billion gallon level the increase is slight. The increase in income to corn producers is balanced, however, by small decreases in the income of soybean producers. Government expenditures are not significantly altered from the *CURRENT* level of $1.6 billion under *GAS-I*. The oil import savings, at first quarter 1979 prices, would be approximately $1.0 billion annually at the 2.0 billion gallon alcohol production level.

It appears that the increased supply of distillers dried grain does not cause a significant drop in soybean prices. As corn prices rise, more corn and fewer soybean acres are planted. The distillers grain, produced as a by-product of the corn conversion to alcohol, contains less protein than the soybeans that could have been grown on the same acreage. An acre of corn produces less protein than an acre of soybeans. As more corn comes into production, displacing soybeans, the supply of protein is diminished, thereby tending to raise protein prices. At the higher levels of alcohol production, the increase in corn acreage in part displaces soybean acreage. The consequent reduction in soybean acreage causes soybean prices to rise at high alcohol production levels.

In summary, differences between the *GAS-I* option and the current program generally are small at the 1.0 and 2.0 billion gallon alcohol production level. This is an important conclusion. It means that up to 2.0 billion gallons of alcohol, which amounts to 2.0% of current gasoline consumption, could be produced from agriculture economically without causing serious adverse impacts in the agricultural sector or elsewhere.

The difference between the results at low and high levels of alcohol production also is quite important. These results indicate that low levels of alcohol production can be achieved for a low resource cost. If we go beyond the 2.0 billion gallon per year output level, however, the resource cost for additional alcohol rises significantly.

Energy and Agricultural Policy

We conclude by relating our results to the analogy between energy and agricultural policy. In recent years, energy policy has moved from surplus to shortage management. Radical changes in energy policy were required to make this policy transition. In a somewhat analogous sense, agricultural policy will require rethinking if our nation decides to produce energy as well as food and feed from agriculture. The inclusion of energy from agriculture as a policy objective within the current policy set—market stability, food security, market development, income protection to producers—would necessitate a rethinking of priorities attached to the expanded set of objectives and the implications of alternative courses of action. The differences in corn and soybean price levels and stability, exports, redistribution of income within the food and agriculture sector, government expenditures, and balance of payments are factors to be considered. In this paper we have tried to indicate some of the options and their impacts on agriculture and energy.

Economics of Electrical Energy from Crop Residue Combustion with High Sulfur Coal

F. J. Hitzhusen and M. Abdallah

The economic feasibility of utilizing corn stover as a coal supplement in small to medium-sized, coal-burning steam-electric plants appears promising, particularly when the low sulfur emission value of corn stover is considered. Two case steam-electric power plants located in Ames, Iowa, and Peru, Indiana, are analyzed utilizing three harvest and collection systems and alternative values for several key technical and economic parameters. These results combined with data from a sample of steam-electric plants in the north central United States are used to assess the potential for this renewable low sulfur energy source.

Key words: corn stover, low sulfur fuel, steam-electric combustion.

The main purpose of this research is to evaluate the economic feasibility of utilizing corn stover as a coal supplement in the large number of small, coal-burning, steam-electric power plants in the north central United States. Corn stover is the crop residue remaining after the grain has been harvested. This is consistent with the worldwide search for renewable sources of energy accentuated by the rising price of nonrenewable energy sources (gas, oil, and coal) and their anticipated declining availability. When burned with high sulfur coal, corn stover is a renewable energy source and sulfur emission control material and may result in net liquid fuel savings.

Corn Stover Combustion

The energy content of crops and crop residues results from solar energy captured by plants in the photosynthesis process. Part of that energy is digestible and used as food. The major indigestible part of the plant energy is contained in agricultural crop residues and is a major subset of total biomass. Among crop residues, corn stover has the highest Btu value per unit of weight because of its relative efficiency in utilizing atmospheric carbon dioxide (CO_2) (Roller). The estimated Btu value of corn stover dry matter ranges between 6,500 British thermal units (Btu) per pound (Buchele) to 8,000 Btu per pound (Benson, Starr). The average heat value for coal is 12,200 Btu per pound. For corn stover to be economically feasible as a coal supplement, it must be cost competitive. The cost of producing a certain amount of energy (one million Btu is the conventional unit) from corn stover should be less than or equal to the cost of producing an equivalent amount of energy-using coal. The major task of this research is the determination of the cost of a unit of heat generated using corn stover for a variety of situations and assumptions.

Corn stover contains 0.017% sulfur (0.053 lbs. S_2O/MBtu) and, when burned with high sulfur coal, it functions as an emission control material potentially to meet the air pollution standards of the Environmental Protection Agency (EPA). The EPA air quality standards differ from one state to another but, generally speaking, coal of more than 1% sulfur (1.639 lbs. S_2O/MBtu, on the average) is considered "low quality coal" (Dugan). Further, 62% of the higher sulfur coal reserves in the United States are found east of the Mississippi, where 90% of the coal-fired power generation occurs. To meet the EPA sulfur emission standards, it is necessary for coal-burning power plants east of the Mississippi to import western coal, or use stack scrubbers, fluidized beds, or some other technology which may be more expen-

Helpful comments were received from Leroy Hushak, Richard Tybout, Edward Ives, and Lynn Forster, and from an anonymous reviewer.

sive than supplemental corn stover combustion.

In the north central United States, corn has the highest residue production of all crops grown (Stanford Research Institute). Moreover, this region is a net importer of energy and most of its coal reserve is high sulfur coal that does not meet EPA emission standards when burned alone or without treatment. For example, more than 50% of the coal in the state of Ohio, which has a considerable share of the coal production in this region has over 4% sulfur content.

Corn stover is also a soil erosion control material. It provides soil nutrients, and it also can be used for livestock feed and bedding. In determining the feasibility of corn stover as a coal supplement, the benefit of reducing the sulfur emissions externality resulting from burning high sulfur coal and the external and private costs (soil and nutrient loss) associated with the removal of stover from the soil should be considered. Other costs include the real and opportunity cost of harvest, storage, and transport of the stover. This is in contrast to limited previous research on the feasibility of stover as a fuel. Buchele and Starr analyzed stover as a fuel but did not account for some of the externalities and used engineering-type cost estimates for harvest and transport rather than opportunity costs.

Two case studies of coal-burning, steam-electric power plants chosen from the population of power plants in the north central states are used for the analysis of this problem. The Peru, Indiana, power plant is chosen to represent the numerous small plants (50 tons of stover/day) which may have limited potential for resource recovery from solid waste or garbage (Hitzhusen, Shenk, Rivet). The Ames, Iowa, power plant, converted in 1975 to use solid waste, represents slightly larger power plants (150 tons of stover/day); its operators have experience in the combustion of solid waste with coal.[1] The selection of these two power plants also represents the two most common types of boilers: the pulverized coal boiler and the stoker boiler. The Ames, Iowa, power plant has both types of boilers and Peru, Indiana, has the pulverized coal type of boiler, which is the most common in the region.

[1] In the north central states, 43% of the coal-burning, steam-electric plants have potential corn stover combustion capacity of 100 tons per day or less. Approximately two-thirds of the plants have less than 250 tons per day of stover combustion capacity. Approximately 9% of the plants have over 2,000 tons per day of corn stover combustion capacity. A stover combustion capacity of 150 tons/day with coal in a pulverized coal boiler represents a combustion capacity of approximately 400 tons/day of coal alone.

Objectives

The general objective of this study is to assess the economic feasibility of using corn stover as a fuel supplement for coal in steam-electric power plants in the north central United States.

The specific objectives are: (*a*) to determine the economic feasibility of harvesting, storing, transporting, and firing corn stover as a fuel supplement in two steam-electric plants; (*b*) to perform sensitivity analysis on the major variables such as coal prices, costs of collecting and firing stover, stover Btu content, changes in technology and the level of throughput; and (*c*) to extend the results of the case studies and sensitivity analysis to the north central states using a sample of power plants.

General Methodology

Because of the lack of a market price for corn stover, break-even point analysis is found to be the most appropriate methodology to determine the feasibility of corn stover as a fuel supplement for coal. The market for corn stover is conceptualized as having a supply (farm sector), a demand (power plant sector), and a transportation sector to link supply and demand. The quantitative relationships that determine the break-even points of each of the three sectors are formulated. The interaction between the three sectors makes up the complete model that determines the feasibility of stover as a supplemental fuel.

Farm Sector

The farmer will not supply his stover to the power plant unless he is paid at least his opportunity cost. This is the break-even point of the farm sector. This cost is composed of the harvest cost, the storage cost, and the net value of the stover itself. The net value of stover is the nutrient content of stover, plus the value of stover for erosion control and livestock feed and bedding, less any reduced costs in tillage associated with stover removal.

It is difficult to quantify the value of stover as an erosion control material based upon the

available data. Schrader, Pesek, Schaller; and Gupta et al. argue that there is a safe limit of stover removal that leaves the soil intact depending upon the type of soil, the slope of the land, and the soil conservation practices. Consultation with agronomists and agricultural extension agents in the localities of the case studies (Ames, Iowa, and Peru, Indiana) was used to determine the total amount of stover that could be removed safely for feed, bedding, and fuel. The same consultations were used to determine the proportion of total stover needed for livestock feed and bedding. The maximum amount of stover available for use as a fuel is the difference between the total amount that can be safely removed and the amount needed for livestock feed and bedding adjusted for a machine harvest efficiency of 64%. This procedure implicitly assumes zero erosion control costs and with the machine efficiency adjustment provides a conservative estimate of available stover for energy. Assuming that farmers will not remove more than the surplus residue, the opportunity cost of the removed stover is the cost of the fertilizers (nitrogen, phosphorus, and potassium—N, P, K) it contains.

For the savings in reduced tillage, only stalk-chopping costs are considered. Plowing and discing costs may be reduced in some cases because of the removal of stover, but these savings are not considered to avoid overestimation of the feasibility of stover as a fuel.

Based on the foregoing considerations, the farm sector relationship is formulated as follows:

$$(1)\quad \text{Min } PsF/MBTU = CH + CS + NVS,$$

where Min $PsF/MBTU$ is minimum price the farmer can accept for the amount of stover that generates one MBtu of heat, CH is harvest cost for the amount of stover that generates one MBtu of heat, CS is storage cost for the amount of stover that generates one MBtu of heat, and NVS is net value for the amount of stover that generates one MBtu of heat, i.e., the savings of foregone chopping costs minus the fertility loss.

The most common types of equipment for harvesting stover in the north central region are the stacker, the large round baler, and loose chop. Farm sector costs are estimated for these three systems of stover harvest. Each system of harvest has different associated transportation and firing systems. Farm storage costs also differ with the harvest system. To identify the least-cost system, the stacker, the large round baler, and the loose chop costs are estimated and compared.

Power Plant Sector

A power plant will not use the corn stover as a fuel unless it costs the same or less than the cost of using coal per unit of heat value. The break-even point of the power plant sector is the maximum price the power plant can pay for stover. This maximum price is the cost of using coal less any costs associated with the use of corn stover in the power plant.

The cost of using coal is composed of the delivered cost of coal, the handling and processing costs, and the sulfur emission control costs (if any). The costs associated with the use of corn stover at the power plant are the necessary modifications of the boiler(s), storage, and conveying costs.[2] The maintenance and operating costs of these installations are also part of the costs associated with the use of corn stover as a power plant fuel. Based upon these costs, the relationship of the power plant sector is as follows:

$$(2)\quad \text{Max}PsP/MBTU = Pc + PRc + Ec - CUS,$$

where Max$PsP/MBTU$ is maximum price the power plant can pay for the amount of stover generating one MBtu of heat, Pc is price of coal per MBtu, PRc is processing costs of coal per MBtu, Ec is sulfur emission control costs per MBtu, and CUS is cost of using stover per MBtu. This is composed of capital costs (amortized using the flow method of capital depreciation), maintenance, and operation costs. The per unit capital cost assumes utilization of full modified boiler(s) capacity.

To conform to the EPA sulfur emission standards, the Ames, Iowa, power plant is blending high sulfur Iowa coal with low sulfur Colorado coal. The other case study (Peru, Indiana, power plant) would use the same

[2] Emission monitoring of refuse-derived fuel (RDF) and coal combustion at the Ames Municipal Power Plant by U.S. EPA showed mixed results. Particulate emissions both increased and decreased with increased percentage of RDF, depending on boiler unit and boiler load. No monitoring of corn stover combustion has been done. Thus, the RDF particulate results at Ames were the basis for assuming no additional costs would be incurred for particulate emission control with the combined combustion of corn stover and coal.

method if required to conform to the standards set for it. To impute the value of stover as a sulfur emission control material, a linear programming model is used. The model is solved with and without corn stover, assuming a zero price for corn stover. The solution is constrained by EPA-imposed sulfur emission standards, by a plant heat production constraint and by a maximum stover/coal-firing ratio for each MBtu of heat produced by boiler type.[3] The difference between the cost of the coal blend with and without the stover is the "shadow price" or the value of stover as a sulfur emission control material.

The general form of the model is as follows:

$$\text{Min } C = \sum_{i=1}^{n} X_i P_i,$$

subject to

$$\sum_{i=1}^{n} S_i X_i \leq S,$$

$$\sum_{i=1}^{n} H_i X_i = 1\ MBTU,$$

$X_1\ H_1 \leq .2\ MBTU/MBTU$-produced (suspension-fired),
$X_1\ H_1 \leq .5\ MBTU/MBTU$-produced (stoker-fired),

where Min C is minimum cost of the blend generating one MBtu of heat; X_i, amount of fuel i in pounds; P_i, price of fuel i per pound (price of corn stover assumed to be zero); S_i, sulfur dioxide content per pound of fuel i; S, sulfur standard set for the power plant (lbs. S_2O/MBtu); H_i, heat content of fuel i (Btu's/lb.); n, number of coal and stover fuels; and 1, corn stover.

Transportation Sector

Transportation of stover from the farm to the power plant could be handled several ways. The stover could be delivered to the power plant by the farmer or picked up at the farm by the power plant. In either case, a custom hauler could be used. If the stover is delivered to the power plant, the relevant transportation distance is the radius of the circle or "stover shed" from which enough stover can be collected to meet the power plant capacity or level of throughput.[4] In this case, the farmer at the margin will determine the price of stover and the farmers located closer to the plant will earn a rent. If the stover is to be picked up at the farm, the appropriate hauling distance is the weighted average distance from the stover shed to the plant. To present conservative estimates of feasibility in the initial analysis of the two case studies, it will be assumed that the stover is delivered to the power plant. In the subsequent sensitivity analysis, it will be assumed that the stover is picked up at the farm.

The other components of transport cost are the loading and unloading costs and the cost per loaded mile. The total transportation cost function is as follows:

(3) $TRPC/MBTU = LUC + CLM \times D,$

where $TRPC/MBTU$ is total transportation cost/ MBtu, LUC is the loading and unloading costs of the amount of stover that generates one MBtu, CLM is cost of hauling the amount of stover that generates one MBtu for one mile, and D is hauling distance required to meet plant capacity.

The Complete Model

The break-even point of the system is realized when the summation of the farm sector cost/MBtu and the transportation cost/MBtu is equal to the maximum price the power plant can pay for stover per MBtu.

(4a) $CH + CS + NVS + LUC + CLM \times D = Pc + PR_c + E_c - CUS$, or

(4b) $CH + CS + NVS + LUC + CLM \times D - Pc - PR_c - Ec + CUS = 0.$

If equation (4b) is less than or equal to zero, stover is assumed to be feasible as a coal supplement. If it is greater than zero, stover is infeasible at 1977 prices of coal.

Data Collection

Data on corn stover is available from the Stanford Research Institute (SRI) in *Crop, Forestry, and Manure Inventory for the United States.* Although this source contains detailed and comprehensive data on crop residues in

[3] Based on consultation with boiler engineers and power plant managers, the maximum stover/coal firing ratio is assumed to be 20/80 for the suspension-fired boiler and 50/50 for the stoker boiler.

[4] This analysis assumed that the power plant sector will operate at full estimated stover and coal combustion capacity. If this assumption is relaxed, the margin of the stover shed is where delivered price at the plant equals harvest and transport costs plus farm value of the stover.

the United States, it has some limitations, particularly regarding corn residue. The SRI data assumes 55% of the corn stover is fed to livestock. Consultation with agricultural extension agents in Story County, Iowa, and Lancaster County, Nebraska, and animal scientists and agronomists at Ohio State, Iowa State, and Nebraska Universities reveals that the amount of stover fed to animals in the Corn Belt probably does not exceed 10% of the stover produced annually. Calculating the maximum amount of stover that could be fed to the livestock in the north central states also showed that 55% is too high for most of the north central states. The SRI data has been adjusted, based upon the maximum quantity of stover consumable by livestock. This revision also overestimates the amount of stover fed to livestock but it is closer to reality than the SRI base data.

The estimates of the costs for the farm and transport sectors are developed primarily from custom rates. Custom rates are published annually by the Cooperative Extension Services of the land grant universities in the north central states. Table 1 presents the average custom rates for hay harvest and transportation for Indiana and Iowa. An effort was made to get the actual custom rates in the localities of the two case studies (Ames, Iowa, and Peru, Indiana) but such data were not available. However, the county extension agents in Story County, Iowa, and Miami County, Indiana, felt that the average custom rates were close to the custom rates in their counties.

The cost estimates for the power plant conversion for corn stover combustion were provided by Gordon Smith, a consultant engineer from Akron, Ohio, experienced in conversion of power plants to fire solid waste. Generally, the estimates reflect costs comparable to those encountered in modifying coal-burning boilers for firing solid waste with coal. Exceptions include addition of a grate to pulverized coal boilers and reduced processing costs due to the absence of metals in corn stover. Cost data on the processing of stover were provided by Farmhand, Inc., Jeffrey Manufacturing Company, and Battelle Columbus Laboratories. A different processing system was specified for each of the three harvest systems. Detailed capital and operating cost estimates for harvest, transport, processing, and plant modifications are developed in Abdallah (pp. 50–76).

Price of coal, type of coal, sulfur and Btu content of coal, and the EPA standards set for each case power plant were provided by the management of the two power plants analyzed and are summarized in table 2.

To attempt to apply the results of the two case studies to other power plants and associated stover sheds in the region, fifty-three power plants were randomly chosen from the power plant population in the north central states. Data on coal prices, custom rates, power plant stover capacity and availability were collected for each of the fifty-three power plants and associated stover sheds and are presented in Abdallah (pp. 170–73). This sample represents approximately 22% of the population of power plants in the region.

Results of the Ames Case Analysis

The Ames power plant is already converted to burn solid waste. It has two stokers and one pulverized coal boiler. To reduce the sulfur emissions of the high sulfur Iowa coal, this power plant is using low sulfur Colorado coal to conform to the EPA sulfur standards.

Table 1. Average Custom Rates in Indiana and Iowa for Three Harvest and Transport Systems, 1977

	Indiana			Iowa		
	3-Ton Stack $/Stack	Large Round $/Bale (1500 lbs.)	Loose Chop $/Ton	3-Ton Stack $/Stack	Large Round $/Bale (1500 lbs.)	Loose Chop $/Ton
Harvest	23.00	11.90	8.84	18.10	7.70	9.48
Transportation

Table 2. Summary Characteristics of the Coal Used in Ames, Iowa, and Peru, Indiana, Power Plants, 1977

	BTU Content (Btu/lb.)	Sulfur Content (%)	EPA Sulfur Standard (lbs./MBtu)	Prices ($/ton)
Ames, Iowa[a]			5	
Iowa coal	9,345	5.5		17.71
Colorado coal	12,000	0.5		32.51
Peru, Indiana[b]			6	
Indiana coal	11,000	4.0		26.50
Colorado coal[c]	12,000	0.5		36.00

[a] Personal interview with power plant managers, summer, 1977.
[b] Personal interview with power plant managers, winter, 1977.
[c] The price of Colorado coal for the Peru, Indiana power plant is estimated based on discussion with three coal shipping companies located in Columbus, Ohio.

The stover combustion capacity of one of the stoker boilers is 150 tons per day. To compare the results of the analysis of the stoker boiler with the pulverized coal boiler, a 150 ton per day level of throughput also is used for the pulverized coal boiler.

Four scenarios are analyzed for this power plant: stoker boiler without emission control costs, stoker boiler with emission control costs (*Ec*), pulverized coal boiler without emission control costs, and pulverized coal boiler with emission control costs.

The farm, transportation, and power plant sector costs are estimated for each of the four scenarios. The cost of sulfur emission control is imputed using the linear programming model discussed earlier. The capital cost of modifying the power plant is amortized using 5%, 9%, and 13% interest rates as part of the sensitivity analysis. However, the 9% rate is assumed to be the most likely or appropriate rate of interest over the life of the project.

By adding the farm and transportation sector costs and subtracting the maximum price the power plant can pay, the feasibility of stover is determined. Table 3 summarizes the results of the break-even point analysis for the four scenarios considered for the Ames power plant (150 tons/day throughput) at the 9% interest rate on capital and 1977 prices of coal. A positive value reflects an economically feasible or "better than break-even" alternative.

Excluding the sulfur emissions control costs from the cost of using coal at the Ames power plant, corn stover is not feasible even for the least-cost harvest system (the stack) and the stoker boiler, which costs less to modify than the pulverized coal boiler. Including the sulfur emission control costs, the stack-harvested stover is feasible for both types of boilers (table 3). More detailed development of the Ames case results is presented in Abdallah (pp. 81–106).

Results of the Peru Case Analysis

This power plant has three pulverized coal boilers and uses Indiana coal which does not meet the EPA sulfur standards. The level of stover throughput estimated for the largest boiler is fifty tons per day. As with the Ames power plant, the analysis is conducted for the Peru case for the farm, transport, and plant

Table 3. Economic Feasibility of the Ames, Iowa, Power Plant (150 Tons/Day) Scenarios at 9% Interest and 1977 Prices of Coal

	Max. Power Plant Price—Farm and Transportation Costs in $/MBtu			
	Stoker Boiler		Pulverized Coal Boiler	
	Without Ec[a]	With Ec	Without Ec	With Ec
Three ton stack	−0.249	0.164	−0.292	0.101
Large round bale	−0.414	−0.001	−0.457	−0.139
Loose chop	−0.629	−0.216	−0.672	−0.470

[a] Ec refers to sulfur emission control costs.

sectors at three interest rates using 1977 prices of coal. Because this power plant has only pulverized coal boilers, only two scenarios are considered: pulverized coal boiler with and without sulfur emissions control costs.

Without sulfur emission control costs, stover is not feasible for this power plant at the 9% interest rate (table 4). The system also is not feasible or does not break even at 5% interest on capital. Including the sulfur emission control costs (assuming this power plant has to conform fully to EPA sulfur standards) the stack-harvested stover is feasible only if the interest rate on capital is 5%. At 9% interest on capital, it falls short of feasibility by \$0.018/MBtu, i.e., if this power plant used corn stover as a supplemental fuel, it would incur a loss of \$0.018/ton if it internalized the sulfur emission control costs and paid 9% interest rate on capital. More detailed development of the Peru case results is presented in Abdallah (pp. 106–21).

The main factors that contribute to the relatively higher feasibility of stover in Ames, Iowa, than in Peru, Indiana, are the lower custom rates and the lower per unit modification costs at Ames. Modification costs are lower at Ames because of the size economies of boiler conversion. The higher level of throughput at Ames yields a lower modification cost per unit of corn stover burned (\$0.295/MBtu) compared to Peru (\$0.476/MBtu) for the same type of boiler (pulverized coal) and the same rate of interest (9%). The per unit modification costs are more than one and one-half times higher at Peru. The economies of size are discussed further in the sensitivity analysis section which follows.

Table 4. Economic Feasibility of Peru, Indiana, Pulverized Coal Boiler (50 Tons/Day) Scenarios at 9% Interest and 1977 Prices of Coal

	Max. Power Plant Price—Farm and Transportation Costs in \$/MBTU	
	Pulverized Coal Boiler	
	Without Ec[a]	With Ec
Three ton stack	−0.318	−0.018
Large round bale	−0.751	−0.456
Loose chop	−0.786	−0.591

[a] Ec refers to sulfur emission control costs.

Sensitivity Analysis

Sensitivity analysis is performed on the major variables that affect the feasibility of stover as a fuel. Specific independent variable or parameter changes required for the system to break even are determined, holding all other parameters constant. The major variables are price of coal, custom rates, Btu content of stover, plant modification costs, level of throughput, changes in harvest technology, and hauling distance.

Independence of the major parameters can be assumed in the sensitivity analysis with the exception of level of throughput which may affect plant modification cost, hauling distance, and/or transport costs. Plant modification costs also might increase as the result of such things as rapid escalation of wages and older plant and equipment. Hauling distance may increase or decrease at a constant level of throughput due to variation in stover density. The price of coal, Btu content of stover, and harvest cost decreases from new technology all can be assumed independent. A separate sensitivity analysis is done on the interrelated variables or parameters.

Table 5 shows the independent variable or parametric changes for the break-even point to be realized at 9% interest on capital for the stack system of harvest at the Ames and Peru plants. The system is generally most sensitive to the independent variables of coal price, stover Btu content, and harvest cost.

For the Ames case to break even without emission control costs, the price of coal has to increase by 22%. If *Ec* are included, the price of coal can drop by 17% and the system would still break even (table 5). Without emission control costs, the Btu content has to increase by 26% before the Ames case can break even and by 25% for the Peru case to break even. If the higher estimate of the stover Btu content of 8000 Btu per pound (used by Starr and Benson) is used instead of 6500 Btu per pound, both cases would be nearly feasible even without including sulfur emission control costs at 1978 prices of coal.

If the harvest cost dropped by 54% (change in technology), both the Ames, Iowa, and Peru, Indiana, cases would break even without including *Ec* (table 5). Such a drop in harvest cost is not impossible. Stover might be combine-harvested with the corn grains in the same operation. This also could reduce the impact of the timeliness problem of stover harvest and fall plowing.

Table 5. Independent Variable Percentage Changes Needed for the Stack System to Break Even at 1977 Coal Prices and 9% Interest on Capital for the Two Case Studies

	Ames, Iowa (150 tons/day)				Peru, Indiana (50 tons/day)	
	Stoker Boiler		Pulverized Coal Boiler		Pulverized Coal Boiler	
Parameter	Without Ec	With Ec	Without Ec	With Ec	Without Ec	With Ec
	(%)					
Price of coal	+22[a]	−17[b]	+36	− 8	+25	+1.2
Modification costs	N.A.[c]	−70	N.P.[d]	−34	−66	−4
Stover Btu content	+26	−12	+36	− 7	+25	+1.2
Hauling distance	N.A.	+107	N.A.	+66	N.A.	−17
Harvest cost	−54	+ 35	−68	+22	−53	−3

[a] (+) refers to percent increase in a parameter needed for the break-even point.
[b] (−) refers to percent decrease in a parameter needed for the break-even point.
[c] N.A., not applicable.
[d] N.P., the break-even could not be obtained even if the parameter is equal to zero.

The system is least sensitive to variations in the hauling distance variable. The Peru case is not feasible regardless of whether the stover is assumed delivered at the power plant or picked up at the farm. The hauling distance can increase by 107% (up to 23.2 miles one way) and the Ames, Iowa, stoker boiler, including the emission control costs, still would break even. Without including the emission control costs, all the cases considered would not be feasible even if the hauling distance is zero.

Sensitivity analysis to test the impact of the size of boiler converted or level of throughput on the per unit cost of firing and transporting the stover (the scale effect) is reported in table 6. Five boiler sizes, or full capacity levels of throughput at 50, 75, 100, 125, and 150 tons per day of stover, are employed to show the scale effect for the Ames, Iowa, stoker boiler.[5] It is found that as the boiler size increases, the per unit modification cost decreases. However, as boiler size increases, the per unit transportation costs also increase. The optimum level of throughput increases with the rate of interest. It is found to be 100, 137, and 168 tons per day, respectively, at the 5%, 9%, and 13% interest rate on capital (figure 1).

The results of the sensitivity analysis and the sample of power plants ($n = 53$) can be utilized to get some notion of the potential of corn stover combustion with coal in steam-electric boilers in the north central states. Information for the sample plants on stover density, harvest and transport custom rates, coal

[5] Extrapolated estimates are made for two additional levels of throughput (175 and 200 tons/day).

Table 6. Stoker Boiler Capital, Maintenance, and Operating Costs and Stover Transportation Cost/MBtu for Five Boiler Sizes (for Stack System)—Ames, Iowa

Power Plant Stover Capacity (Tons/Day)	Required Distance (Miles)	TPC[c] Cost $/MBtu	*KC + MOP*[c] $/MBtu 5%	9%	13%	*TPC + KC + MOP*[c] $/MBtu 5%	9%	13%
50[a]	7.62	0.199	0.269	0.352	0.444	0.468	0.551	0.643
75[a]	9.04	0.217	0.244	0.310	0.334	0.461	0.527	0.551
100[a]	10.10	0.231	0.224	0.282	0.319	0.455	0.513	0.550
125[a]	10.92	0.242	0.206	0.251	0.306	0.448	0.493	0.548
150[a]	11.71	0.252	0.187	0.232	0.283	0.439	0.484	0.535

200[b]	16.54	0.315	0.145	0.180	0.230	0.460	0.495	0.585

[a] Estimates are based upon the data collected for the Ames, Iowa, case study.
[b] The extrapolated estimates shown by the dotted lines of figure 1.
[c] *TPC* is transportation costs, *KC* is plant capital costs, *MOP* is plant maintenance and operating costs.

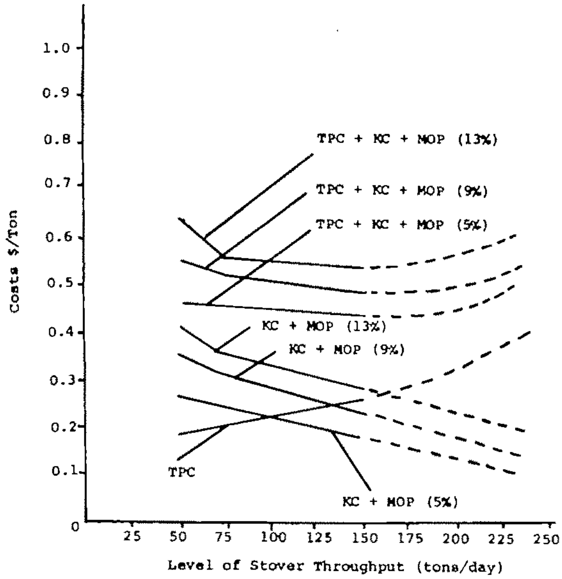

Figure 1. The relationship between the power plant modification and stover transportation costs and the level of stover throughput

prices, sulfur emission standards, boiler type, number and size, combined with the assumption that large multiple boiler plants can convert only part of their capacity to corn stover combustion provides some basis for extending the case study results. It would appear that from one-third to one-half of the coal-burning power plants in the north central states have more favorable, or comparable conditions, for feasibility of stover as a fuel to those of Ames, Iowa.

Assuming that one-half the power plants have more favorable, or comparable conditions, to Ames, Iowa, the proportion of corn stover that could be utilized economically in steam-electric power plants in the north central region could replace approximately 20 million tons of coal or 488 trillion Btu's per year. Although coal and oil are not perfect substitutes, this coal savings is equivalent to approximately 87 million barrels of crude oil per year. This is a large number, but it represents less than ten days of crude oil imports at current levels.[6]

[6] Additional potential exists in the numerous industrial and institutional coal-burning steam-generating boilers located in the north central states. Data are not as readily available on these installations, but in Ohio they are approximately ten times more numerous than coal-burning steam-electric boilers.

Summary and Conclusions

Because of the growing rate of energy consumption, the depletion of nonrenewable fossil fuels is inevitable. Renewable resources, such as biomass, are assumed to be more appropriate sources of energy if they are currently or potentially cost competitive. In this research, the economics of using corn stover as a power plant fuel to supplement coal is investigated in two case study steam-electric power plants: Ames, Iowa, and Peru, Indiana.

If the price of coal increases at a faster rate than the harvesting, transport, and firing costs of stover, the feasibility of corn stover as a fuel at small power plants similar to the Peru, Indiana, plant is foreseeable in the near future. Assuming sulfur emission standards are required to be met, the Ames, Iowa, case is economically feasible at current prices.

The sulfur emission control costs proved to be important for the economic feasibility of stover. If the sulfur standards become more stringent and are more rigorously enforced, stover feasibility would improve. If the proposed requirement of installing stack scrubbers in all the coal-using power plants is imposed, the value of corn stover as a sulfur emission reducing material probably would decline.

The results of the sensitivity analysis reveal that among the independent variables or parameters, the price of coal (including the sulfur emission control costs or higher priced, low sulfur coal), the Btu content of stover and the harvest cost are important determinants of feasibility of stover as a power plant fuel. The optimization of stoker boiler size or level of throughput and the associated transport costs for the Ames case occur somewhere between 100 and 168 tons of stover per day, depending on the rate of interest assumed.

The stack system of harvest proved to be the least-cost system of harvesting and firing the corn stover. The large round bale system involves lower transport cost than the stack system but the stack system is much less costly to harvest and fire at the power plant.

More research is needed on the potential for corn and other crop residues as well as solid waste and forest biomass combustion, particularly in coal-burning industrial and institutional boilers—probably more numerous than steam-electric plants. This work also should attempt to determine any potential net liquid

fuel savings from reduced transport of low sulfur western coal to meet emission standards. Preliminary assessment of these savings looks promising. Further research also is needed on the economic feasibility as well as the energy balance of alternative uses of corn stover and other crop and forest biomass for methane, ethanol, and other thermochemical and biological conversion products. The recent discovery at Purdue University of a more efficient solvent process for the conversion of cellulosic material, such as crop residue, to ethanol (a liquid fuel) may be promising in this regard (Tyner and Bottum).

European Community Agriculture and the World Market

Alan Swinbank

The European Communities' common agricultural policy is more complex than some studies would indicate. Not only do the member states succeed in maintaining nationally preferred price support levels through the use of green currencies and monetary compensatory amounts, but the protective mechanisms applied have a differential impact on some commodities and some supplying countries. The introduction, in 1979, of the European Monetary System had repercussions for the agricultural sector, including the use of a new unit of account.

Key words: common agricultural policy, import levy, unit of account.

For the last twenty-five years economists, civil servants, and politicians have been concerned with the impact of the common agricultural policy (CAP) of the European Communities (EC) on the operations of the world market. Unfortunately, it is tempting to treat the CAP as if it were a single policy applied in a uniform manner in all the member states of the EC. This is an oversimplification which could lead to serious misinterpretation of the CAP. In fact, as this article will attempt to point out, foreign suppliers of temperate zone agricultural produce face at least three distinct forms of protective mechanism. Furthermore, the concept of common support prices within the EC is an illusion; for many commodities there are seven regional price zones. That common EC farm prices do not exist has received extensive attention in the European literature; that not all products or suppliers face the same protective mechanism or degree of protection has received little attention even in Europe. A noticeable exception is Harris, who has attempted to document the various trading relationships. In describing these three "faces" of the CAP, a number of topics worthy of further research will be identified.

The article will be limited to a consideration of temperate zone agricultural products, or products that effectively compete with the output of European temperate zone agriculture. It will not deal with the particular problems of Mediterranean zone produce—issues that are particularly pressing, given the forthcoming enlargement of the EC to encompass Greece and the proposed enlargement to include Portugal and Spain—nor the hierarchy of tariff and other trade concessions conceded by the EC on various tropical products to particular less developed countries.

During 1979 a European Monetary System (EMS) was introduced which will in time modify the details of the CAP, if not its character. In a concluding section, an attempt will be made to sketch the impact of EMS on the farm sector.

The Exchange Rate and Agriculture

In North America, concern has been expressed about the impact of the exchange rate on the farm sector. Thus, Schuh was concerned about the impact of an over-valued dollar on the adjustment problems of U.S. agriculture. An implicit assumption in his analysis was that the farm sector was in some sense more responsive to changes in world market prices—and hence, to manipulations of the exchange rate—than were other sectors of the economy. Thus, if it could be shown that various policies had resulted in an over-valuation of the U.S. dollar, it would follow that there had been a differential impact on the farm sector (in comparison to the other sectors of the economy) which would tend to depress farm earnings and output.

In the EC, concern has also been expressed about the response of farm and food prices to

Alan Swinbank is lecturer in agricultural economics at the University of Reading, England.

exchange rate changes; but in this instance the responsiveness was not due to the inherent characteristics of the economy, but to the mechanism of the CAP price support system. One of the basic principles of the founding fathers of the EC was that free trade should exist within the Community. However, it was also decided that for many farm products—including cereals, sugar, dairy products, beef, and pigmeat—a Community-wide price support system should exist maintained by the paraphernalia of threshold (minimum import) prices and intervention (public purchase) prices. Threshold prices are fixed above intervention prices so that under most market conditions domestic produce enjoys a price advantage over potential imports.

In August 1969, only two years after common EC prices had been established for cereals, the French franc was devalued. If common support prices were to be maintained, then the franc price would have had to increase by the full extent of the devaluation. The effect would have been as if France had faced a perfectly elastic foreign demand for her farm produce, so that on devaluation the domestic price would rise by the full extent of the currency change, whereas, in practice, most sectors of the French economy would face a smaller price effect.

The French government was unwilling to accept a sharp rise in the cost of food and so maintained the level of support at the franc prices prevailing before the devaluation. Common prices no longer existed and the support mechanism in the other member states had to be bolstered by border taxes on exports from France to them, with subsidies on imports into France. These border taxes and subsidies are now known as monetary compensatory amounts (MCAs). France had isolated the farm sector from exchange rate change: in effect, the pre-devaluation exchange rate had continued to be used in the farm sector to determine national price support levels. Thus the "green franc" was developed.

Later in the same year (October 1969) the West German mark was revalued. This posed similar problems for the West German government, but in this instance government policy was directed to avoiding a fall in German farm product prices. Thus a "green mark" came into being and monetary compensatory amounts were levied on German imports and paid on German farm exports.

Despite the disruption to common pricing, both France and West Germany did at the time agree to a return to free intra-Community trade. Thus France agreed to eliminate her green currency over a two-year period. For Germany it was decided that the losses experienced by farmers caused by an early return to common pricing would be compensated in various ways, including a temporary rebate on value-added tax. A select committee of the British House of Lords recently revealed that German farmers would in fact continue receiving some benefit from this concession on value-added tax until the end of 1980 (House of Lords, p. 84).

The dollar "crisis," and subsequent Smithsonian agreement of 1971, exacerbated the problem of trying to maintain common CAP pricing because intra-EC exchange rate movements were evident. Indeed throughout the 1970s intra-EC exchange rate movements have continued. Governments have attempted to maintain stability in farm and food prices; in some cases they have attempted to protect consumers from the consequences of devaluation (e.g., the United Kingdom) or farmers from revaluation (e.g., West Germany). There have been some "devaluations" and "revaluations" of green rates but these have not matched the evolution of the market exchange rates. Consequently, there now exist seven price zones for farm products within the EC, the three Benelux countries having maintained a common level of price support. The German price level has consistently been at the top of the price hierarchy; often 40% above the British price level at the bottom. Table 1 gives an indication of the relative levels of CAP price support in July 1979; the ordering is fairly constant through time, but the absolute levels do vary. The particular figures shown

Table 1. Index of CAP Support Prices, July 1979

Country	
West Germany	119.2
Benelux	110.6
Denmark	107.5
Ireland	105.9
France	102.2
Italy	100.7
United Kingdom	100

Note: Based on MCA percentages applied for most CAP products in July 1979: immediately following final agreement on the 1979/80 price package.

reflect a considerable strengthening of sterling during the preceding weeks.[1]

It has been explained that for many CAP commodities a uniform level of EC price support does not exist; instead there are a number of different national support levels. However, the fiction is maintained that EC prices are common through the device of fixing them in units of account. The unit of account is not a currency, but merely an accounting unit. To convert these "common" prices into national monies the green conversion rates, referred to above, are utilized. Thus, a green conversion rate is an expression relating so many units of a national currency in terms of units of account; and it is because these green conversion rates do not correspond to the market cross-rates between the currencies of the EC member states that different price levels result and MCAs are necessary. At the annual farm price review, ministers are concerned with the level of common prices fixed in units of account and with the green conversion rates for their respective countries (Harris and Swinbank). The unit of account prices determine the relative prices of the different commodities in each of the member states while the green conversion rate determines the absolute level of all prices.

Variable Import Levies and Export Subsidies

To ensure that minimum import prices are respected, variable import levies are imposed. For some products, such as cereals and sugar, these vary on a day-to-day basis, whereas, for other products, the levies are normally fixed less frequently (fortnightly for dairy products, monthly for processed products, and quarterly for pigment, eggs, and poultry meat). Whatever the details of the system the intention is the same: to maintain a constant level of price in each of the price zones regardless of developments on the world market. To permit EC produce to be marketed competitively on world markets, variable export subsidies may be granted.

The levy, or subsidy, will of course differ depending upon the EC member state with which the third country is trading. The net tax or subsidy is made up of two elements: a uniform EC levy or refund which bridges the gap between the world price level and the (largely fictitious) common EC price level, to which is either added or subtracted the same MCA that is applied in intra-community trade. In the case of West Germany this MCA would be an addition to an import levy (if applicable), whereas in the case of the United Kingdom it would act to reduce such an import levy.

This CAP support mechanism, which applies to many farm products, has two consequences for the world market. Many authors have commented that CAP price levels are maintained above the world market price. It is recognized that a relaxation of the price support mechanism within the EC would result in a greater import demand for agricultural produce and thus there would be a tendency for world market prices to rise. Nonetheless, many authors believe that EC price support levels are maintained above the long-run equilibrium level of world market prices and consequently that resource misallocation occurs. A number of authors (for example, Sampson and Yeats) have attempted to measure the effective rate of protection for EC agriculture. However, the protection afforded is variable, not fixed. Thus, even if it were established that the average effective rate of protection for some particular commodity were $x\%$ in some historic period, economists would still have difficulty comparing this with an effective rate of protection of $y\%$ (based on fixed tariffs) on another product.

From a theoretical, and a practical, point of view, the stability of CAP prices—whatever their level—is probably more significant. The nature of the variable import levy and export subsidy system is to maintain unchanged the pattern of EC production and consumption whatever the developments on the world market, even if the supply and demand fluctuations originate within the EC. Even when world market prices exceed EC prices, stability in EC production and consumption might be maintained because variable export taxes can be imposed and—in the case of sugar in 1974–75—variable import subsidies. However, it should be noted that the policy is not exactly symmetrical and the CAP is far more successful in maintaining stability of prices when the world market price lies below EC prices than in the contrary case.

The consequence of the policy—as Johnson noted—is that the EC tends to avoid any share in the burden of accommodating shortages and

[1] A large amount of detail has been omitted from this history, and some events are compressed into one. For a faithful history, see Irving and Fearn; for an analysis of the effect of MCAs on EC agriculture, see Heidhues et al., and Swinbank.

gluts in the world economy. A subset of the world's population must accommodate these changes, and the resulting world market price fluctuations will be greater than they would be if European producers and consumers were involved. Indeed, Josling has shown that if a number of major producing and consuming regions in the world adopt similar measures the level of the world market price could be indeterminate unless stockholding proved to be a significant activity.

It is often asserted that the world market is residual, and therefore unrepresentative, and to support this view the small proportion of production entering into world trade is cited. However, some support policies divorce the domestic market from changes on the world market (e.g., the CAP's variable import levies), whereas others allow domestic producers and consumers to react to changes on the world market (as with tariffs—ad valorem or specific—provided they are not prohibitively high).

On closer examination it might be found that certain world commodity markets are more representative than is commonly supposed because the particular form of protection adopted does permit the transmission of price signals across national boundaries. Thus, the logic of the Schuh thesis is that price formation for farm produce within the United States, and on the world market, is intimately linked. It also should be recognized that the situation is not static. Notwithstanding export taxes and (for sugar) import subsidies it is probable that certain regions of the EC—if not all member states—effectively entered the world market in the commodity boom of the early 1970s.

GATT Bindings on Oilseeds, Manioc, and Sheepmeat

There is a substantial trade in temperate zone (or temperate zone competing) products that escape the variable levy system and so provide a linkage between the EC market and the world market. For various reasons the EC entered into the General Agreement on Tariffs and Trade (GATT) bindings at the time of the Dillon round negotiations such that oilseeds, oilseed products, and manioc enter the EC at zero or very low tariffs and sheepmeat is subject to a 20% ad valorem tariff. It is sometimes reported that the EC much regret these bindings, and in the past there have been various attempts to tax imported vegetable oils. Recently it has been reported that in the future Thailand (the principal supplier) will voluntarily limit the shipment of manioc to the EC.

Commentary on these major exceptions to the CAP price support mechanism has concentrated on the lesser degree of protection afforded these products. Thus the EC's cereals policy is said to be under threat because of the use of cheap oilseed meal and manioc imports in animal feed, and the massive increase in shipments of soya from the United States and manioc from Thailand are cited to support this view. Certainly in the Netherlands feed compounders have made increasing use of these products. Similarly, the EC's dairy policy is said to be under threat on two fronts: cheap oilseed cakes stimulate milk production but skim milk faces competition as an animal feed from soya meal, and butter faces competition from vegetable oils in the form of margarine. Olive oil—another CAP-supported product—also faces stiff competition from vegetable oils. The conclusion that is drawn is that—compared to a free trade model—consumption of these commodities is stimulated in the EC and likewise their production in third countries.

However, one topic which has not been explored is the linkage these products provide between the world market and the EC market. The EC market price for soya rises and falls in response to changes on the world market, and thus the world market price does help determine the EC consumption of soya. But the linkage could well be perverse.

Suppose the world grain supply were to fall, thus driving up world market prices. The CAP price mechanism for cereals would ensure that EC prices remained unchanged, and thus the level of cereal consumption would be maintained whereas in other parts of the world it would fall. Livestock producers in those third countries would tend to switch from cereals to cereal substitutes, such as soya and manioc, and drive up their price. However, this price change would be felt within the EC; it would tend to raise the price of cereal substitutes in relation to cereals and so stimulate the consumption of cereals as animal feed. In Europe there would be a tendency to increase the consumption of cereals, whereas the rest of the world would be limiting consumption to match the available supply.

Sugar and New Zealand Butter

The entry of the United Kingdom into the EC in 1973 posed a number of problems for third country suppliers of farm products, particularly if those products were to be subject to the CAP price support mechanism which is operated to ensure that EC suppliers have first preference on the market. As part of the agreement reached at the time of the United Kingdom's accession, two major exceptions to this rule were agreed. The first was that Commonwealth sugar producers should have a guaranteed price and quantity in the British market. That agreement subsequently was amended to include a number of other less developed countries, and it now provides for the purchase by any member state, at a fixed price, of 1.3 million tons of white cane sugar per annum; more than 10% of EC consumption. Van Kempen recently has concluded an interesting study which deals with sugar in more detail than the following paragraphs, but in a similar way.

The second was to allow the United Kingdom to purchase from New Zealand specified quantities of butter and cheese, at a fixed price, up until the end of 1977. With a change of government in the United Kingdom in 1974, a renegotiation of the terms of entry ensued. This resulted in an extension of the agreement for butter, but not for cheese, until the end of 1980. New Zealand butter currently supplies more than 25% of the British market. As a result of the Tokyo-round negotiations, New Zealand (together with Australia and Canada) again will have access to the EC market for specified quantities of cheese at a given price; and the EC Commission has proposed to the Council that the agreement on New Zealand butter be extended beyond 1980.

The price guarantees involved are somewhat complex and warrant further attention. When the initial agreement on New Zealand dairy products was being concluded, New Zealand and Britain asked that the price guarantee be in terms of pounds sterling. The EC Commission insisted that this could not be the case, and that the price guarantee would be in terms of units of account. Equally, when the present sugar agreement was being drawn up, the guarantee was again concluded in units of account. In retrospect, these decisions can be seen as being highly advantageous to the supplying countries because the unit of account had been defined in such a way that it has increased in value against sterling.

In the 1960s, when the CAP was being assembled in a period of exchange rate stability, the unit of account was given the same gold value as the U.S. dollar. The devaluations of the dollar against gold in 1971 and 1973 were thus treated as devaluations against the unit of account. However, in 1973 a number of EC currencies began a joint float against the dollar (and other world currencies); and to maintain the European character of the unit of account, its value was linked to the joint float currencies. The introduction of the European Monetary System has involved certain modifications as outlined below.

As the joint float currencies floated against the dollar, so did the unit of account. The dollar value of the unit of account is tabulated in table 2. As the years have gone by, a number of different units of account have been defined. The one that is tabulated here, the EUR, is sometimes referred to as the agricultural unit of account. If all green conversion rates had been fully "devalued" or "revalued," they would have had these dollar values. In the next section the European unit of account (EUA) and the European Currency Unit (ECU) will be discussed. It can be seen from table 2 that since 1973 the dollar value of the EUR has varied considerably, depending upon the relative weaknesses and strengths of the dollar and the European joint float currencies on world money markets. The weakness of the dollar in relation to the EUR in 1978 is particularly evident.

The dollar value of the price guarantees to New Zealand and the sugar suppliers reflected the changing value of the EUR. The price guarantee has two parts: first, the market price in the United Kingdom where the product must compete with EC supplies; and second, an MCA subsidy paid on import to compensate for the fact that sterling had depreciated against the EUR.[2] Thus, instead of an unchanged guarantee in sterling, the sterling equivalent in fact increased as sterling fell against the EUR. In table 3 an attempt has been made to tabulate the impact of the price guarantees on the unit earnings.

In columns a and d of table 3 it is indicated that the EC in fact has increased the price guarantee for both products over the years, though it is widely reported that a deal was negotiated with New Zealand in 1976 which

[2] In the case of butter the New Zealanders themselves undertake shipment to the United Kingdom, but the sugar producers are in a weaker position in that they rely on the sugar traders to pass back the import subsidy.

involved a higher price in exchange for a smaller quantity. Over the period in question, sterling has fallen in value in relation to the unit of account, and so the sterling price guarantees from the British market have evolved as in columns b and e. In columns c and f, the U.K. retail price index is tabulated. It will be seen that the sterling price guarantees have largely kept up with the rate of inflation in the United Kingdom, although the strength of sterling in 1979 has reversed that trend. It is of course true that these countries will have transport costs to pay, will not wish to purchase only British goods, and will not wish to purchase the range of goods represented in the U.K. retail price index; but as a first approximation, it does appear as if the price guarantees maintained their real value until early 1979.

An assessment of the benefits (or costs) of the EC's import concessions to the various sugar producers and New Zealand would have to measure the impact on the total export earnings of these countries for the products in

question, not just the earnings on sales to the EC. Deductions would have to be made for transport costs because the guarantees apply in EC ports, and then the real purchasing power of the net export earnings assessed. Many of the sugar-producing countries, and New Zealand, sell substantial quantities of produce on world markets. If the EC subsidizes the export of some quantity of the produce, and so depresses world market prices, then it is, in effect, reducing the value of the price guarantees offered to the sugar-producing countries and New Zealand.

Units of Account and the European Monetary System (EMS)

As the 1970s progressed, exchange rate movements within the EC led to pressure on three fronts. First, as we have seen, the concept of common prices within the CAP was shattered. Second, the definition of the unit of account proved to be too inflexible to absorb the changes taking place; and so, in 1975, a new unit was introduced: the European unit of account (EUA). Finally, the Europeans' aspiration for economic and monetary union, which had seemed to be receding, was revived in 1978, when a new political initiative was launched. This led to the establishment of EMS in the spring of 1979.[3] These three interrelated topics each have some significance for the foreign observer of EC agriculture.

The EUA was an attempt to define an EC measure which would reflect the changing values of member states' currencies, weighted in some appropriate fashion. It is literally a "basket" of currencies as is shown in table 4. Each of these constituent parts are valued in terms of Belgian francs on a daily basis thus giving the EUA's value in Belgian francs. Subsequently, the value of the EUA in terms of any other world currency can be determined.

The first sphere of EC activity in which the EUA was used concerned various measures associated with the EC-ACP (African, Caribbean, Pacific) convention of Lomé. In January 1977, the Statistical Office of the European Communities, in its publications, began using this new unit. For a two-year period (1975–76) the EUR had been used in statistical series; and prior to that the unit of account data published by the Statistical Office had been derived from national price data using the pre-Smithsonian IMF (International Monetary Fund) par values. Although the Statistical Office did, of course, revise the entire series of price data, subsequent editions of a particular publication contain the same series in a different form.

An appreciation of the confusing array of units of account perhaps can be gleaned from the following example. If, in December 1978, the intervention price of a particular product had been 100 units of account, this would have been equivalent in the United Kingdom at the then green rate to £63.42. Translated back into a statistical series, this would have become either 78.01 EUR or 94.39 EUA. Great care always should be taken, when using price statistics, that the units of account are properly defined and are consistent with other price data.

The decision to inaugurate EMS, on the one hand, implied the demise of the joint float (and hence the EUR) and, on the other, gave a central role to the EUA (rechristened the European currency unit—ECU). Thus the debate, which had continued for some time as to whether the EUA should be introduced into the agricultural sector, was brought to a conclusion. There were in essence two features of the new unit of account which caused problems for the CAP. The EUA (or ECU as it was now known) had a lower value than the EUR and so, if it had been introduced on a one-for-one basis, the theoretical "common" price level would have been correspondingly reduced. There was at no time any real intent that national price levels would be changed,

[3] The provisions of EMS were briefly described in the *Economist*, 17 March 1979.

for green conversion rates would continue to be used as before. However, such a change would have altered the basis for calculating monetary compensatory amounts because, for example, the German price level would then have been much further away from, and the British closer to, the "common" price level. This difficulty was overcome by applying a coefficient to both prices and green conversion rates so that there was no net change. (The coefficient was 1 EUR = 1.208953 ECU.)

The second difficulty arises from the fact that, over time, the "basket" unit of account is liable to be a weaker measure of value than the EUR. This is thought to be the case because the EUR was defined in terms of currencies which in the past have tended to appreciate on world currency markets, whereas the ECU is composed of a basket of all EC currencies, some of which in the past have tended to depreciate. This has led to the fear that CAP price levels might be eroded over time unless offset by corresponding increases in the common price level. It is probable that EC farm groups will be well able to defend their own interests; but the question does arise as to what in practice will happen to the price guarantees for imported dairy products and sugar. It is not possible to predict with any degree of certainty how the ECU will perform in relation to the EUR, or how generous (or parsimonious) the EC will prove to be in revising price guarantees to overseas suppliers.

These difficulties were complicated by a French demand that the introduction of EMS should herald the progressive dismantling of the MCA system and a genuine return to common CAP prices. The reluctance of the other member states to accede to this demand resulted in the delayed inauguration of the new currency system. However, it remains to be seen whether the compromise agreed upon will have any significant effect on CAP pricing. EMS is much less than an economic and monetary union; it is more akin to a European Bretton Woods system with fixed but adjustable exchange rates. It well may lead to a more stable monetary environment in which the day-to-day problems of running the CAP are reduced; but as yet it does not imply the convergence of economic performance which many observers would view as a necessary condition for return to common CAP pricing.

Conclusions

In this essay an attempt has been made to show that the EC's CAP has many facets, all of which impinge upon third country suppliers and the world market. In particular, three "faces" of the CAP have been identified: the archetypal system of variable import levies and export subsidies; the particular regime applying to oilseeds, manioc, and sheepmeat; and the price guarantees to certain overseas suppliers of dairy products and sugar. It is hoped that sufficient material has been documented to show that studies of the CAP should pay attention to detail.

Price Behavior on a Declining Terminal Market

William G. Tomek

The relationship of prices of choice steers on the Denver terminal market to comparable prices on the Omaha market apparently was influenced by the sharp decline in saleable receipts in Denver. But price effects of the volume of trading were measurable only when the volume in Denver became extremely small in 1967 and 1968. These results are consistent with defining a thin market place by using sampling concepts. Some subtleties of using Chebyschev's inequality to define a thin market are discussed.

Key words: Chebyschev's inequality, markets, price discovery, sampling, steer prices, thin markets.

Thin markets may create problems in pricing farm products. One concern is that a small volume of trading at a central market place can result in price behavior not warranted by economic conditions. Moreover, deliberate manipulation of prices is more feasible with a small volume. If the central market quotations are used as base prices in other transactions, the problems of unwarranted or manipulated prices acquire increased economic importance.

Research and writing on thin markets can be categorized under five questions. First, what is a thin market? Second, why do markets become thin? Third, if a market becomes thin, what are the consequences, if any, for price behavior? Fourth, if price behavior is influenced, what is the mechanism or linkage between market volume and price behavior? Finally, if thin markets have adverse consequences, what solutions exist for the problem? Although a considerable general literature exists on thin markets (e.g., Hayenga), there is little specific information or empirical evidence on these questions. In this context, this paper has two objectives: to develop a more precise definition of thinness and to investigate the effects on price behavior of a declining volume of trading on a central market. In addition, the linkage between volume and price behavior is discussed briefly.

The empirical application is for choice steer prices in Denver, a terminal market that declined and disappeared. Steer prices in other locations are used as a standard of comparison. This paper, however, is essentially a search for hypotheses and an exploration of methods, and the empirical results should not be interpreted as definitive conclusions about price behavior on thin markets.

Defining and Analyzing Thin Markets

A major concern about thin markets is that the number of transactions (per unit of time) is so small that "unwarranted" price behavior occurs. The warranted price is usually defined in terms of the perfect competition norm. Prices may deviate from the norm because of deliberate manipulation or poor information. The issue of manipulation, however, is difficult to analyze with the data typically available. Observations on the actions and motives of individual traders are probably needed.

The issue of poor information perhaps can be analyzed with existing, secondary data. A declining volume of transactions implies less information and perhaps lower quality information. In a perfect market, a single equilibrium price exists for a given quality product at one location at a point in time (say, a day). A single transaction price, however, contains

William G. Tomek is a professor of agricultural economics, Cornell University.

The paper was written while the author was a visiting economist, Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture, and their support of the research is gratefully acknowledged.

M. L. Hayenga, J. Hassler, R. G. Heifner, K. H. Kahl, J. S. Mann, K. E. Nelson, and T. D. Mount provided helpful comments on an initial draft. The author, of course, accepts full responsibility for the final content.

some error relative to the unknown equilibrium; the error may be large or small; the magnitude is unknown. An increase in the number of transactions within the time period increases the information available. Conversely, as volume declines, the quantity of information declines.

Information may be defined statistically as the reciprocal of the variance. If, as is assumed below, the average of transactions prices is an estimate of the true equilibrium price, then the variance of the mean of transactions prices decreases as the number of transactions increases (but see note 1). In this sense, the intuitive notion that fewer, publicly reported prices reduce information is consistent with statistical theory.

In addition, the quality of information may decrease. For example, a meat packer maintains a knowledgeable buyer at a market place with a large volume. The buyer has available the resources of the firm as well as his experience. With a declining volume, the cost per transaction of maintaining an experienced buyer at a particular location increases, and this buyer may be withdrawn. (Of course, other reasons may exist for the processor leaving the market.) Thus, the quality of information probably is reduced, and this poorer information may be translated into poorer price behavior. This argument does not necessarily suggest a bias in prices, but rather, larger errors in price formation.

Much of this paper deals with changes in prices with the passage of time and differences in prices among locations. The price discovery process is one of finding the warranted adjustments from existing levels as expectations about factors determining price change. Price changes are thought to follow a random walk or martingale process in a perfect market (Samuelson); but, for the purposes of this paper, the question is how may the number of transactions influence the discovery of warranted price changes? Intuitively, this number may not be a constant. An unexpectedly large change in supply, for example, may require more transactions to discover the correct change in price than does a small change in supply.

Defining a Thin Market

Chebyschev's inequality perhaps can help provide a specific definition of a thin market. One statement of the inequality (e.g., Cramer or Mood) is

$$P(|X_n - \mu| \geq c) \leq \frac{\sigma_n^2}{c^2},$$

where P defines the probability of the expression, and c is an arbitrary constant. X_n is a random variable with mean μ and variance σ_n^2. The subscript n is added to emphasize that X_n and σ_n^2 depend on n. For example, X might be an individual transaction price. Hence, X_n would be the mean of transactions prices for particular time period and σ_n^2 the variance of the distribution of the mean. One of the advantages of using Chebyschev's inequality is that it is applicable to distributions of random variables with finite variances. The results do not require that the distribution of prices or price differences be normal.[1]

In the inequality, μ can be treated as the true, but unknown, equilibrium price for given economic conditions (though this is not the definition used in most of the paper). Two views exist in the literature about the relationship of actual transactions prices X to the equilibrium μ. One is the $E(X) = \mu$; the mean of observed prices is treated as an unbiased estimate of the equilibrium. Some mixed evidence, based on experiments, exists about this assumption (Hess, Smith). In any case, the assumption implicit in most econometric models is that the average reported prices are equilibrium prices.

The tâtonnement process is a second concept for relating the X's to μ; prices progressively converge toward equilibrium (for a recent review, see Paul). Then, X_n is the last price in a series of n transactions and is the estimate of equilibrium. Again, one can ask, how many observations are needed to obtain a "precise" estimate of the population param-

[1] This paper does not discuss distributions of prices, but the topic is important for estimating the number of reported transactions needed for accurate pricing. Distributions of price differences on futures markets may not have finite variances (Mann and Heifner), but Samuelson hypothesizes that the variances of price differences on futures markets increase as the maturity of the futures approaches. In any case, this paper deals with changes in cash prices. Cash prices typically have been assumed to be distributed normally with constant variances. But the assumption of normality is based on an appeal to the Central Limit Theorem rather than on empirical analyses, and the analysis in the text suggests the variance is not constant. If the assumption of a normal distribution is accepted, then the probability of a particular level of precision could be greatly reduced relative to Chebyschev's inequality. For example, if $c = 2\sigma_n$, then by the inequality $P \leq .25$. For the normal distribution, $P \leq .05$. The use of Chebyschev's inequality can be justified as a conservative approach. On the other hand, the normal distribution is often assumed, and with estimated variances, the t distribution can be justified.

eter? A tâtonnement process, however, typically is not observable in real world data, and from a practical viewpoint, the average of transactions prices must be used.

Thus, defining a thin market is equivalent to finding the number of transactions, n, required to obtain a "large" probability that X_n is "close to" μ. To find n, Chebyschev's inequality may be rewritten as

$$P(-c \leq X_n - \mu \leq c) \geq 1 - \frac{\sigma^2}{nc^2}.$$

For the mean X_n to be within the range $-c$ to $+c$ to μ with probability P,

$$P = 1 - \frac{\sigma^2}{nc^2} \text{ or } n = \frac{\sigma^2}{(1-P)c^2}.$$

Alternatively, if an existing market or pricing arrangement has n transactions (per unit of time) with a particular variance, then the implied precision of pricing in terms of P and c can be estimated.

This framework suggests, first, that the definition of a thin market is somewhat arbitrary. It depends on the definitions of "large probability" and "close to," i.e., on c and P. A second implication is that the concept of a thin market is a relative one, given c and P fixed while σ varies. The number of transactions, n, will vary as σ varies if a fixed standard of precision is used.

From a sampling viewpoint, increasing n increases costs. From a price discovery viewpoint, the cost relation is less clear. Given N total transactions per day, n of them at a terminal market, thereby contributing to public information, little empirical research exists to explain why n is declining, although some obvious hypotheses exist. (It costs market participants less, say, to formula price based on a central market quotation than actually to participate on the central market.) Hence, a question arises about the trade-off between precise prices and the number of transactions, n. This is an area for fruitful research, but cost topics are not explored in this paper.

The discussion to this point has emphasized intraday or daily prices assuming fixed economic conditions. Obviously, with the passage of time, economic conditions and equilibrium prices change. Prices also vary, of course, with quality and space. In this context, the parameter μ can be interpreted as the true price difference (through time, between regions, or between qualities). The remainder of this paper uses, almost exclusively, price changes or differences. The unit of time also is important in defining a thin market. This paper considers day-to-day and week-to-week changes—the time periods usually considered in the thin market literature.

Measuring Performance

Measuring the performance of a thin market is a problem, in part, because the perfectly competitive norm is not observable. There are likely to be problems in developing a usable norm. Price differentials that should prevail under competitive conditions can be computed, and observed differentials can be compared with the computed values. For example, the differences in economic value of different yield grade carcasses can be computed based on the differences in saleable retail meat, and then actual price differences can be compared with the true economic differences (Trierweiler and Hassler).

Equilibrium price levels, of course, are not observable. In principle, an econometric model could be constructed and estimated. If the model were correct, it would provide unbiased estimates of equilibrium prices under stated conditions. However, most econometric models pertain to quarterly or annual observations and not to the daily or weekly prices of interest in thin markets. Moreover, it is always difficult to build correct models and especially difficult to model short-term prices. But, for short-term prices, the random walk model can be used as a norm (Mann and Heifner).

In this paper, prices on the Omaha market are used as a norm in the study of Denver prices. Omaha is, in effect, treated as a proxy for the national market. During the period under analysis, Omaha had a large volume of cattle sales, including choice steers, but of course no market is perfect. Imperfections are a matter of degree. Thus, while differences in performance may exist between markets, they may not be sufficiently large to be measurable by available data and statistical methods. On the other hand, if differences in price behavior are found, they could be due to factors other than differences in volume of trading. While such problems can not be solved, the Omaha market also was compared with the Sioux City market. The volume of choice steer sales remained reasonably large in Sioux City during

the sample period while the Denver market expired. Thus, Omaha prices can be compared with another large market and with a declining market place.

Data and Procedures

The Denver central market is potentially an interesting case study. In the mid-1950s, about 850 thousand cattle were marketed per year in Denver; well over 200 thousand were slaughter steers. By 1968, only 10 thousand steers were marketed, and in late 1968, volume was so light that price reports were sporadic. In November 1967, the market shifted to auction pricing of cattle, and the Agricultural Marketing Service discontinued price reporting for steers on the Denver market on 1 January 1969. It closed in 1972. While cattle marketings declined in all central markets especially after 1965, the volume in the late 1960s and early 1970s in Omaha and Sioux City was still greater than in Denver in the 1950s. Clearly the Denver market place became thin by any standard, while the volume in Omaha and Sioux City in the 1950s and 1960s seems adequate for price discovery purposes.

Prices were collected for choice, 1,100–1,300 pound steers at Omaha and Denver, for the 1955–68 period. The same prices were also obtained for Sioux City for selected years within this period. The range of prices on Monday of each week was recorded. Monday has had a large volume of slaughter steers relative to other days of the week. If Monday was a legal holiday, then Tuesday prices were used. Thus, each year has fifty-two or fifty-three observations, the number of Mondays per year.

The availability of prices only as a daily range raises questions about the comparability of the prices between markets. During the sample period, the instructions to market reporters were to give the range between good and prime steers based on market conditions for the day (not necessarily the range of actual transactions). Thus, the intent was for the midpoint of the price range to represent the midpoint of the range of quality of choice steers. The midpoint of the range is used in much of the analysis.

However, for thirteen of the fourteen years in the sample period, the range of daily prices in Omaha was on average wider than in Denver. The Omaha range was especially large during the early years, and it tended to narrow with the passage of time. This is a bit puzzling because market reporters in both locations had similar instructions. Literally interpreted, the data imply that the gap between good and prime steer prices was consistently larger in Omaha than in Denver. Another possible explanation is the difference in reporters' interpretations of the range of choice prices. Given that Denver had relatively few prime cattle, there also may have been few high choice steers causing the Denver reporter to focus upon a slightly lower grade than in Omaha. Some analysis was done using the low of the range on the assumption that these prices may be more comparable in the two markets. The low in Denver tended to decline relative to the low in Omaha. There is no clear trend in the differences of the midpoint, though this difference was quite large the last year of trading in Denver.

The data were plotted and evaluated visually; and the means, standard deviations, and coefficients of variation were computed by year and by month within years. The principal descriptive statistic presented is the coefficients of determination (r^2) for both price levels and first differences.

Regression models were also considered. The Denver and Omaha prices probably should be viewed as simultaneously determined; though, because Omaha is a much larger market, and because Denver is in a later time zone, causation each day may run more from Omaha to Denver than vice-versa. Because of transportation costs, prices in two locations can be somewhat independent of each other; Denver prices could move in a band about Omaha prices defined by transfer costs. Given these considerations, a simple model for the two markets is

$$(1) \qquad D_t = \Pi_0 + \Pi_1 M_t + \Pi_2 X_t + u_t$$

$$(2) \qquad M_t = \lambda_0 + \lambda_1 D_t + \lambda_2 Z_t + w_t,$$

where D is Denver price of choice steers on Monday; M, Omaha price of choice steers on Monday; t, Mondays (weeks); X, predetermined local conditions in Denver; and Z, predetermined local conditions in Omaha.

The problems of fitting equation (1) or (2) are the simultaneity of D and M and whether X and Z can be observed. Obvious candidates for X and Z are the receipts of choice steers in the respective markets on each Monday. Unfortunately these data are not available, though total receipts of cattle are. They were

not collected, however, when the price data were obtained.[2]

The Denver-Omaha price differences had a systematic pattern (were autocorrelated), and this probably is related to different patterns of marketings of steers in the two markets. Models that allowed for seasonality or trend were explored, and results for a first difference equation are presented.

$$(3) \quad D_t - D_{t-1} = \gamma + \beta(M_t - M_{t-1}) + v_t.$$

This equation was fitted by year and for selected pooled periods. The intercept can be viewed as a proxy for an omitted variable, and gamma is a measure of regional price differences used in the next section. Although the Durbin-Watson statistics were usually reasonable, equation (3) presumably is a misspecified version of equation (1), and likewise, while causation may run more from Omaha to Denver than the reverse, simultaneous equations bias probably is present in the least-squares estimates. Thus, the estimated parameters likely are biased, though alternative model specifications made little difference in the estimated slope coefficients. With these limitations in mind, emphasis is placed on descriptive statistics.

Empirical Results

An expression derived from Chebyschev's inequality is used to estimate whether or not Denver and Omaha might be considered thin markets. In

$$n = \frac{\sigma^2}{(1 - P)c^2},$$

P and c are selected rather arbitrarily. Emphasis is placed on obtaining an appropriate measure of the variance, σ^2, for the questions at hand. In this paper σ^2 estimated from Omaha prices is used for establishing n related to the change in the price level of choice steers. For Denver, the appropriate σ^2 relates to changes in price differences between Omaha and Denver.

Because the price level need not be rediscovered, a variance based on the first difference of prices is a sensible measure of the variability of the random variable in question. That is, μ for Omaha prices is defined as the change in true equilibrium prices, and σ^2 is estimated from the first differences of observed Monday prices by year.[3] This implies that week-to-week changes in the equilibrium are being analyzed. This variance overstates the difficulty of the market's problem because Omaha prices are available on more than one day per week.[4] In addition, as already discussed, the Chebyschev relation gives a fairly large n relative to assuming a precise distribution of price changes. On the other hand, σ^2 is estimated from market data and is not the true variance. Moreover, a variance based on Monday-to-Monday changes in the midpoint may understate the complexity of discovering the full range of prices from low to high choice steers. The values of n estimated should be treated as the approximations that they are.

For the computations, c was set equal to 10 (cents per hundredweight) and P to 0.9. The value of c is in the context of standard deviations of the first difference of Omaha prices that were often about 50¢ per hundredweight, though the range was from 21¢ to 69¢ for the years in the 1955–68 period. The values for c and P are also convenient in that $(1 - P)c^2 = 10$. Thus, the computed n is just the variance of the first differences of Omaha prices divided by ten. These values are shown in column one of table 1. In interpreting results, the reader should remember that they apply to discovering the price change for 1,100 to 1,300 pound choice steers and that the variance of Monday-to-Monday prices is based on a calendar year sample. In addition, the results are for a specific location, but they are "national" in the sense that they apply to changes in price level and not to changes in regional or quality differentials.

Because the first differences are from Monday to Monday, the estimated n may be inter-

[2] Available time and resources did not permit collection of the quantity observations subsequent to the collection of the price data. Moreover, the addition of seasonal dummy variables or the use of first differences had surprisingly little effect on the estimated slope coefficients, and the specification error bias may be small. Thus, the payoff to collecting market receipts data for total cattle marketings (another proxy variable) is unclear.

[3] The variance is computed from the Monday-to-Monday change in the midpoint of the range of prices. An alternative estimate of the variance could be obtained from the intraday range of individual prices. Assuming a symmetric distribution of prices within the range and given a typical range of $2 per cwt., the approximate standard deviation would be 48¢ per cwt. This value resembles the standard deviations computed from the first differences of midpoints.

[4] Steer prices were usually available on two or three days per week in Denver in the early and mid-part of the sample period, and this number declined to one per week and finally to zero per week. In any case, the collection of daily prices would have greatly increased cost of analysis. Hayenga suggested that one might study market thinness by analyzing prices on days with small volumes.

Table 1. Estimated Number of Transaction Prices for Choice Steers Required to Establish Accurate Price Changes

Year	Price Level Change	Denver-Omaha Difference
	(number per week)	
1955	277	61
1956	337	87
1957	176	70
1958	229	90
1959	193	37
1960	196	49
1961	133	44
1962	224	55
1963	262	65
1964	474	58
1965	243	32
1966	255	42
1967	94	34
1968	45	37

Note: See text for definition of accuracy.

preted as the number of prices (lots or transactions) required for establishing precise week-to-week price changes. The number is not directly comparable with saleable receipts because a typical lot would contain about twenty-five steers (though a lot size down to one is possible). To estimate an equivalent volume in terms of annual saleable receipts, the number of transactions is multiplied by twenty-five animals per lot and by fifty-two weeks. Thus, saleable receipts range from 58,500 in 1968, a year with small week-to-week price variability, to over 616,000 in 1964, a year of large price variability. These receipts are to maintain a precision of plus or minus 10¢ per hundredweight around the true change in mean prices with a 0.9 probability.

In the 1955–68 period, the saleable receipts of choice steers in Omaha ranged from 384 to 570 thousand, and these receipts typically were sufficient to meet the accuracy standard. They are clearly sufficient because the receipts in other markets also help determine the overall level of steer prices. For example, 991 thousand choice steers were sold in Omaha and Sioux City combined in 1964, the year with the largest "requirement" for transactions.

As stated earlier, steer prices are determined simultaneously, but for simplicity, the Omaha-Denver data are used to estimate the number of transactions required in Denver to discover precisely the change in the differential between Denver and Omaha. The differential in question is

$$\mu = (\mu_t^D - \mu_t^M) - (\mu_{t-1}^D - \mu_{t-1}^M),$$

where μ^D is equilibrium price in Denver, μ^M is equilibrium price in Omaha, and t, $t - 1$ is current and previous weeks.

To estimate n, the variance of $\hat{\mu}$ is needed. An estimated difference for a particular week is

$$\hat{\mu}_t = (D_t - M_t) - (D_{t-1} - M_{t-1}), \text{ or}$$
$$(D_t - D_{t-1}) = \hat{\mu}_t + (M_t - M_{t-1}).$$

For a year ($t = 1, \ldots, 52$), an estimate of an average μ and its variance can be obtained from the first difference equation (3), where the notation is changed so that $\gamma = \mu$. The parameter β is thought to equal one, though in practice it may not. In this paper, $\hat{\gamma}$ and its variance are obtained as least-squares estimates of (3).

The level of precision is defined as $P = 0.9$ and $c = 2$, and

$$n = \frac{\hat{\sigma}^2}{(0.10)(4)} = \frac{\hat{\sigma}^2}{.4},$$

where $\hat{\sigma}^2$ varies from year-to-year using equation (3). The level of c is set at a smaller level for the precision of the change in the regional differences than for the change in the price level, but the specific value 2 has no special justification.

The estimated values of n are given in column 2 of table 1, and n ranges from 32 in 1965 to 90 in 1958. As before, n can be interpreted as the number of transactions per week to establish precise changes in regional price differences from week to week. The equivalent annual saleable receipts range from 42 to 117 thousand choice steers. Although data are available only for total steer sales in Denver, receipts in the 1955–66 period appear adequate to discover precise price differences. In 1967 and 1968, however, about 48,000 head of steers would have been required each year for precise price discovery. In contrast, actual receipts were 28,000 and 10,000 steers of all qualities.

Chebyschev's inequality is not needed to demonstrate that the Denver market was thin in its last years, especially 1968. The application, however, does illustrate the complexity of the issue. Moreover, the results suggest that the price effects of a thin market, if any, are likely to be measurable only in 1967 and in 1968. In previous years, volume seemingly was adequate for fairly accurate pricing.

Price Behavior

This paper takes the position that the principal effect of the number of transactions is on the precision of pricing, and a number of measures of precision based on the weekly observations were explored. No simple relation was found between statistics like the range, standard deviation, or coefficient of variation of prices and market volume (e.g., table 2). The effect of volume was obvious in one respect: namely, weeks existed in late 1968 without reported prices for choice steers in Denver ($n = 0$).

The use of r^2, however, does suggest some imprecise price behavior associated with market volume. The coefficient of determination between Omaha and Denver prices was always above 0.81 (for weekly prices by year) from 1955 to 1967, but declined to 0.71 in 1968. For the first differences of prices, r^2 was usually above 0.5 in the 1955–66 period; r^2 for the first differences declined to 0.29 in 1967 and 0.04 in 1968 (table 3).

The first difference equation (3), as discussed, is of interest because the intercept coefficient provides a measure of the average change in regional differentials from week to week by year, and the model is also a way to take account of positive autocorrelation. The slope coefficients of equation (3) with Denver prices dependent tend to decline from the mid-1960s to the termination of the market. The first difference results are summarized by pooling the observations into two groups of years 1955–66 and 1967–68 (table 4). The average slope in the earlier period is 0.79 and in the final two years 0.46. Using the F-test for differences in models over time, the two equations are statistically different at the 5% level; however, given the heteroscedasticity apparent in the residuals of the individual year equations as well as other statistical problems, the hypothesis test should be taken with a grain of salt. Nevertheless, the results for equation (3) and for equations with seasonal dummies (not shown) clearly suggest a changing slope coefficient as market volume declined in Denver.

Table 2. Coefficients of Variation for Choice Steer Prices and Saleable Receipts of Slaughter Steers

	Coefficients of Variation[a]			Number of Steers		
Year	Denver	Omaha	Sioux City	Denver	Omaha	Sioux City

Table 4. First Difference Regressions for Pooled Years

Years	$\hat{\gamma}$	$\hat{\beta}$	r^2	d
1955–66	0.145 (1.402)[a]	0.794 (0.028)	0.562	2.49
1967–68	0.455 (2.657)	0.463 (0.097)	0.204	2.45

$F = 3.016$ (for hypothesis that regression parameters are equal in the two periods, numerator degrees of freedom = 2, denominator = 710).

Note: First difference of Denver prices dependent and first differences of Omaha prices independent variable (¢/cwt.)
[a] Standard error of coefficients in parentheses.

The foregoing evidence, of course, does not prove an association between performance and volume. One way to strengthen or weaken the case for the thinness of the Denver market is to compare Omaha prices with a market that still had a large volume in the sample period. Thus, choice steer prices in Sioux City were analyzed for the years 1958–61 and 1967–68, inclusive. These years were selected because they cover the range of results from the regression analysis of the Denver-Omaha relationship. Not surprisingly, the data show a close association between Omaha and Sioux City prices (tables 2 and 3). The correlations are near one, and the coefficients of variation are similar.

Perhaps the simplest way to compare the Denver and Sioux City markets is through the first difference regressions. The first differences of the midpoint prices for Sioux City are regressed against the first differences of Omaha prices (table 5), and these results can be compared with those for the Denver-Omaha equations. In the 1958–61 period, the Sioux City-Omaha and Denver-Omaha equations are qualitatively similar. In 1961, the hypothesis $\beta = 1$ cannot be rejected for both equations. In 1959 and 1960, the slope coefficients differ from one for both equations.[5] In 1958, the Sioux City equation has a slope different than one and the Denver equation does not, but the slope for the Sioux City equation, like Denver, has a magnitude greater than in 1959 or 1960. The r^2 coefficients are similar. In 1967 and 1968, however, the Sioux City-Omaha equations clearly differ from the Denver-Omaha equations in terms of slope coefficients and r^2's. These results strengthen the view that the precision of pricing in Denver was influenced by declining market volume.

The question of possible bias is more difficult to analyze, but the apparent differences in the seasonal pattern of marketings in the two regions (near Denver and Omaha) were used to explore the issue. In figure 1, the vertical axis is the difference between Omaha and Denver steer prices on average, by month, for the years 1961–65. These years were selected because the regression analyses suggested a close one-to-one relation between Omaha and Denver prices in this period after adjusting for seasonality. (The hypothesis that the true slope equalled one cannot be rejected in the regressions including seasonal dummies.) The horizontal axis of figure 1 measures regional differences in supply, which are approximated by using regional slaughter data for all cattle. Specifically, the sum of slaughter in the Mountain and Pacific regions is subtracted from the slaughter in the Northwest portion of the North Central region (includes Iowa and Nebraska). The dots in figure 1 are the average 1961–65 differences by month, and an inverse relation exists.

The exercise was repeated for the individual months October 1967 to September 1968, the last twelve months with complete weekly price data. This period is represented by the crosses in the figure. Obviously the relationship shifted to the right. For a given level of supply—a fixed difference in slaughter—Denver prices are lower relative to Omaha than in the earlier, base period. This is consistent with the possibility of the Denver market providing prices that are biased downward for given economic conditions. This may be related to the small volume in Denver, but an

[a] Midpoint of choice steer prices on Mondays in cents per hundredweight. In each equation, the first difference of the Omaha price is the explanatory variable.
[b] Standard errors of coefficients in parentheses.
[c] Denver observations available only for thirty-eight continuous weeks. Sioux City equation uses same time period.

[5] Taken as a whole, all of the results indicate unusual price behavior in 1959 and 1960. In Sioux City-Omaha equations using price levels, the intercepts are two standard deviations above zero. In the first difference equations, the slopes differ from one. For the Denver-Omaha equations, the slopes are consistently below one. Since years before and after have the expected relationships, the performance in 1959 and 1960 is a puzzle. The answer to the puzzle is not within the scope of this paper.

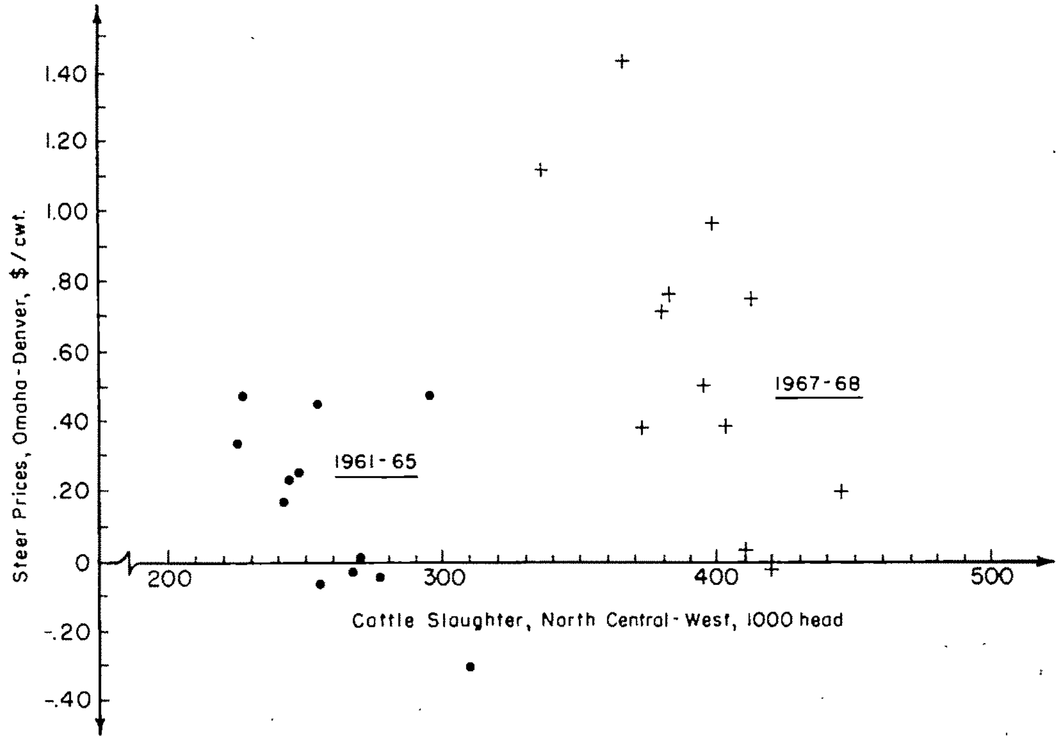

Figure 1. Regional differences in steer prices versus regional differences in cattle slaughter

exhaustive investigation of this hypothesis would require construction of a spatial equilibrium model, an analysis beyond the scope of this paper. Moreover, the regional supply variables used here are crude, and errors in measuring these variables may account for the shift.

Concluding Observations and Qualifications

This paper defines thinness by analogy with sampling concepts from statistics. This approach establishes a (perhaps arbitrary) standard of precision (price behavior), and then estimates the number of transactions required to obtain the standard. The approach has the advantage of defining what is meant by "precise" price behavior and of emphasizing the relative nature of defining a thin market. The structure of prices is exceedingly complex, however, and it may be difficult to estimate the number of transactions, n, required to avoid thinness. (An alternative application is to estimate the precision implied by existing volume, n.)

Given the complexity of establishing prices for live cattle, the number of transactions required to discover steer prices with considerable precision seems small to me. Apparently thirty to thirty-five transactions per Monday (about 50,000 steers per year) were adequate under the conditions of the 1960s to discover Denver prices rather precisely relative to the Omaha price. If a specific assumption were made about the distribution of price changes, the number would be even smaller.

The reader, however, should not be overly reassured by these results. Since the 1960s, commodity prices have become more variable. If a fixed standard of precision is maintained, such as 10¢ per hundredweight, then the number of public transactions must increase with the variance. In contrast, the trend has been toward declining volumes on central cash markets.

Estimates of the variance of changes in daily or weekly price from a sample of fifty-two weeks may be inappropriate for estimating n. The variance presumably should reflect changes in the current forces determining prices. If there is little reason for prices to change, then few transactions are needed to achieve a given level of pricing precision (and vice-versa). Thus, a sample based on a calendar year may not be from a population rele-

vant for estimating the variance needed for obtaining n. Intraday prices or a shorter period may be more appropriate (but see note 4). Also, prices varied little in the 1955–68 period relative to the 1970s, and even for the period studied, the variances of weekly prices by years were unstable. The question of an appropriate sample period for estimating a relevant σ^2 is not fully answered in this paper.

In interpreting the results, the distinction between a market and a market place or a market channel must be kept in mind. Denver was just one market place in a national cattle market. Thinness in Denver does not, of course, necessarily imply thinness in the market in general. But, to the extent publicly reported prices are needed to establish regional or quality differentials, a problem of thin markets may remain. The Denver market place became a poor place to discover regional prices for choice steers relative to the Omaha market place. Because, during the period studied, fed cattle production was growing in Colorado, regional price differences were probably better established in a market channel other than the Denver terminal market, but it may be more costly to obtain public price reports from channels other than central markets. If the principal role of publicly reported prices is to establish a known, national base for other transactions, then the increased volume of trading on futures markets may assist in establishing an accurate base (Cox).

Another issue is whether the items priced on the central market are representative of the full population of items being sold. It is alleged, for example, that the lots sold on central markets tend to be lower quality than the typical lots of the product. The observed prices may not be a random sample of the population prices. For pricing, however, a random sample may be unnecessary. If the items priced on a central market are of a known quality, then the price established for that quality can be used to price other quality products. The remaining prices need only establish the correct difference. Thus, bias is permitted if a correction factor can be obtained, but the assumption $E(X) = \mu$ rules out the use of manipulated prices in estimating the true equilibrium.

With respect to performance of prices on a terminal market, thinness can mean that no transactions occur over extended periods of time. Consequently, the descriptive statistics, such as the mean and variance, become more difficult to interpret. For the period with continuous price series, r^2 between Omaha and Denver prices declined, and the slope coefficient moved further from one. From a technical statistical viewpoint, this does not necessarily mean prices are biased; rather one may say that prices are established with less precision as volume declines. Individual prices and their averages have larger errors, but these errors can be offsetting so that, on average, there is no bias.

In evaluating the results, it is not appropriate to talk in terms of formal hypothesis tests. A given data set was subjected to many exploratory analyses, thereby reducing levels of significance (Wallace). Nonetheless, the results are clearly compatible with the hypothesis that declining volume results in imprecise pricing. This is the implication of the analysis of Denver prices, strengthened by the Sioux City results. Moreover, logic alone suggests that declining information will result in larger pricing errors.

Given the historical nature of the analysis, the empirical results are not immediately applicable to a current problem, but the results do seem to point toward useful methods of studying thin markets.[6] It may be possible to estimate the number of transactions required for a given level of pricing precision or to estimate the precision implied by the existing volume. Such estimates can be sharpened over those of this paper, if convincing evidence is provided that price changes have a specific probability distribution and if an appropriate sample can be ascertained for estimating σ^2. Other research needs to consider the costs of improving pricing precision and to suggest less arbitrary ways of defining the precision parameter, c. For example, the concept of price risk might enter into defining c. Many of the problems of analysis found in this paper seem surmountable, and analyses of current issues, such as the pricing of beef carcasses, could be attempted.

[Received May 1979; revision accepted January 1980.]

[6] Several reviewers have suggested that the sampling analogy gives a misleading definition of a thin market. For example, the mere use of number of transactions misses the possibility that one transaction may contain more information than another; all transactions are not equal in the amount or quality of information provided. But such an objection might be overcome by extending the results of this article to include stratified sampling, or if nothing else, particular markets might be analyzed in terms of their ability to provide judgment samples. In the author's view, it is important to develop a concept of a thin market that has empirical content. The sampling framework is one approach to empirical analysis, and hopefully readers will be motivated to make extensions and improvements.

The Impact of Component Pricing of Soybeans and Milk

Richard K. Perrin

Currently, the price that an individual farmer receives for soybeans is not adjusted for oil and protein content, and the price for milk is adjusted for fat content but not for solids-not-fat. This study finds that the potential social surplus gains from a change to component pricing of these commodities is small (no more than one to two percent of current commodity value, before deducting the extra costs of such a pricing system). Substantial transfers would occur between component-consuming groups, while producers as a group would be affected only slightly.

Key words: component pricing, milk market, soybean market.

It is in the nature of many commodities, particularly agricultural commodities, that quality varies from batch to batch. Where the dimensions of quality are easily discernable, market prices presumably will vary from batch to batch to reflect quality differences; but where information about product quality is expensive to obtain, market participants may be willing to transfer a commodity batch with very little information about the quality of that particular batch. In the latter case the market prices may only weakly transmit to the producer the consumers' preferences for various aspects of product quality, which in turn suggests that social welfare gains could be achieved if information about the quality of each batch could be obtained at sufficiently low cost. The purpose of this paper is, first, to show how an increase in the accuracy of price transmission would affect equilibrium prices, quantities, and social surplus in the markets for a commodity for which value is determined by the amount of and market prices for the components contained in a particular batch. The market for such a commodity is somewhat simpler than those generally considered by the literature on hedonic prices, where product quality dimensions are not decomposed and priced separately, as they are here. The second objective of the paper is to estimate the size of the potential equilibrium displacements which would occur in the markets for soybeans and milk, if these commodities were priced on the basis of perfect information about the components contained in each batch traded. The interest in these two commodities arises from the introduction in recent years of electronic scanning devices which may substantially lower the cost of obtaining information about component content.

Richard K. Perrin is professor of economics and business at North Carolina State University.

Journal Paper No. 6231 of the North Carolina Agricultural Research Service.

The author is indebted to Nelson Updaw, Everett Nichols, several other colleagues, and two anonymous reviewers for helpful comments and suggestions in the development of this study.

The Economic Model

The market to be analyzed is that of a commodity whose market value derives solely from two components in the commodity, call them component A and component B. The objective is to compare the market equilibria which would exist under two pricing institutions. The first I will refer to as "commodity pricing," in which the price per unit of the commodity is not adjusted to reflect component content. The second I will refer to as "component pricing," in which the commodity is exchanged on the basis of the value of components A and B in the commodity batch being exchanged.

The two market equilibria are illustrated in figure 1. The production possibilities curve is labeled PPC. Producer equilibrium is determined by the ratio of implicit prices which they receive for the two components, designated as w_a and w_b. First consider the condi-

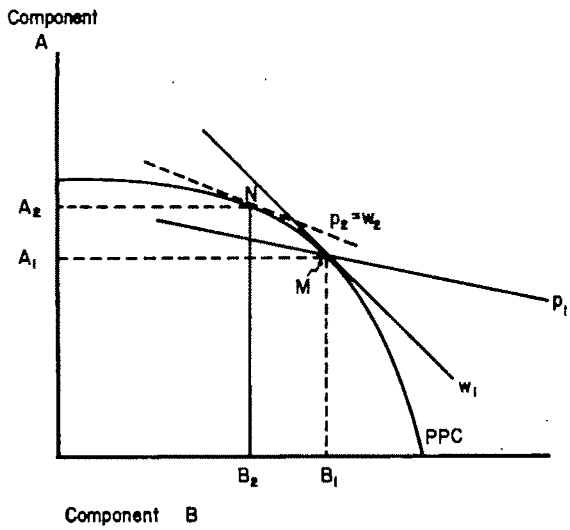

Figure 1. Commodity pricing and component pricing equilibria

tions for equilibrium under commodity pricing. Producers are paid the commodity price for their product, regardless of component composition. Therefore, the ratio of implicit component prices, w_a/w_b, is equal to 1.0, and the slope of the iso-revenue line (w_1 in figure 1) is -1.0. Point M therefore indicates the equilibrium levels of component production, A_1 and B_1, under commodity pricing. The component prices for this equilibrium, p_a and p_b likely will exhibit a ratio different from 1.0, because those prices are determined by consumer demand in the component markets, given the levels of production A_1 and B_1. Thus, under commodity pricing a wedge separates the two price ratios p_a/p_b and w_a/w_b. Now, if component pricing were implemented, a new equilibrium would occur at some point such as point N, where the component price ratio and the implicit producer price ratio are equal to each other and to the marginal rate of transformation between A and B. Compared to the equilibrium M, the component pricing equilibrium N will result in more production of A, the higher priced of the two components, and the component price ratio p_a/p_b will have fallen to a level below its original level but still greater than 1.0, the original ratio w_a/w_b.

A relevant question is why commodity pricing could occur as an equilibrium in a competitive market, given the incentives for arbitrage implied by the divergence of the price ratios w_a/w_b and p_a/p_b. A plausible explanation is that the screening and transactions costs necessary to monitor the component content of each commodity batch sold may exceed the potential arbitrage returns. If this is the case, the commodity pricing equilibrium is socially as well as privately optimal, despite the price transmission wedge. Improved technology eventually may reduce these screening and transactions costs sufficiently to induce a change to component pricing. While it would be useful to pursue an analysis of the equilibrium level of information about commodity quality (as in Kihlstrom, for example), such an analysis is beyond the scope of this paper. For this paper, the more limited objective is to analyze the potential effects on producers and consumers should component pricing be costlessly implemented.

Next, the impact of component pricing versus commodity pricing is analyzed in greater detail with a more complete specification of the market. First we specify that components A and B are produced jointly, using a vector of inputs Z, and that the production function $\phi(A, B, Z)$ is groupwise additive in outputs and inputs, that is, $Q(A,B) = G(Z)$, where $Q(A,B)$ represents transformation between components, and $G(Z)$ represents substitution among inputs (see Christensen, Jorgenson, Lau, p. 31). By suitable scaling, Q and G may be measured in units of the commodity. The function $Q(A,B)$ is assumed homogenous of degree one in A and B.[1] The nature of the function G is of no particular interest in component pricing analysis, except to note that a fixed level of inputs Z gives rise to a production possibilities frontier that is fixed, such as the one in figure 1. Supply conditions in the Z markets, however, give rise to a supply curve for the commodity, $f(p)$, permitting the production possibilities curve to shift in and out.

A complete set of equations describing the industry equilibrium is as follows:[2]

(1) $Q = f(p)$,

(2) $Q = Q(A,B)$,

(3) $w_a = pQ_A$,

(4) $w_b = pQ_B$,

(5) $A = p_a(A)$,

(6) $B = p_b(B)$,

[1] While the assumptions of additivity and homogeneity are plausible over a limited range of the production function, they certainly would be questionable over very wide ranges, as pointed out by a reviewer.

[2] This formulation and the subsequent analysis was suggested by the approach of Muth.

(7) $\gamma = (p_aA + p_bB)/w_aA + w_bB),$

(8) $\rho = (w_a/w_b)/(p_a/p_b).$

The first equation specifies the supply of the commodity, the second is the production function, while the third and fourth specify producer equilibrium in the production of components A and B (given the implicit prices they face, the supply price of the commodity itself, and the partial derivatives of the transformation function, Q_A and Q_B.) Equations (5) and (6) specify equilibrium in the consumer markets, given the demand curves $p_a(A)$ and $p_b(B)$. The seventh equation describes what can be generally interpreted as the percentage processing margin—the ratio of the value of the components sold in the component markets to the value received by producers.[3] Equation (8) is an identity which defines the size of the price wedge between producers' and consumers' markets. Under component pricing it is assumed that no wedge exists, so that $\rho = 1$. Under commodity pricing, ρ may take on any positive value.

We now proceed to establish the effect on equilibrium prices and quantities of an exogenous change in ρ from its equilibrium level under commodity pricing to 1.0, the equilibrium level which would exist under component pricing. Displacements from equilibrium can be expressed conveniently in terms of percentage changes in the variables, designated here with the operator E, *i.e.*, $EA = dA/A = d\ln(A)$. Total differentiation of equations 1, 5, and 6 yields:

$$(1') \qquad \frac{1}{e} EQ - Ep = 0,$$

$$(5') \qquad \frac{1}{n_a} EA - Ep_a = 0,$$

$$(6') \qquad \frac{1}{n_b} EB - Ep_b = 0,$$

where e is the elasticity of supply of the commodity and n_a and n_b are elasticities of demand for component A and component B. The differentiated form of equation (7) can be expressed conveniently in terms of component shares, where k_a and k_b are the component shares $k_a = w_aA/(w_aA + w_bB)$, $k_b = w_bB/(w_aA + w_bB)$, and s_a and s_b are component shares $s_a = p_aA/(p_aA + p_bB)$, $s_b = p_bB/(p_aA + p_bB)$. Then given the identity

$$(9) \qquad E(w_aA + w_bB) = \frac{1}{w_aA + w_bB} \{w_aAEA + Aw_aEw_a + w_bBEB + Bw_bEw_b\},$$

and assuming for ease of analysis that the processing margin is constant ($E\gamma = 0$), the differentiated form of (7) may be expressed as

$$(7') \qquad (k_a - s_a)EA + (k_b - s_b)EB + k_aEw_a + k_bEw_b - s_aEp_a - s_bEp_b = 0.$$

Differentiation of (8) is direct and yields

$$(8') \qquad Ew_a - Ew_b - Ep_a + Ep_b = E\rho.$$

To express the differentiation of equations (2) and (3) conveniently, it is useful to draw upon three properties of functions, such as $Q(A,B)$ which are homogeneous of degree one:

property (a): $AQ_A + BQ_B = Q,$

property (b): $Q_{AA} = -\frac{B}{A}Q_{AB},$

property (c): $\tau \equiv \dfrac{E\left(\frac{A}{B}\right)}{E\left(\frac{dA}{dB}\right)} = \dfrac{Q_AQ_B}{QQ_{AB}},$

where τ is by definition the elasticity of transformation and is negative for convex production frontiers.

By definition:

$$(10) \qquad EQ(A, B) \equiv \frac{1}{Q} (Q_AAEA + Q_BBEB).$$

Then from property (a) and the equilibrium conditions (3) and (4),

$$(11) \qquad EQ(A, B) = k_aEA + k_bEB,$$

and therefore the differentiated form of (2) can be expressed as

$$(2') \qquad EQ - k_aEA - k_bEB = 0.$$

Finally, note that by definition,

$$(12) \qquad EQ_A \equiv \frac{1}{Q_A} (Q_{AA}AEA + Q_{AB}BEB).$$

Invoking properties (b) and (c), this may be expressed as

$$(13) \qquad EQ_A = \frac{k_b}{\tau} (-EA + EB),$$

[3] Equations (3) and (4), along with the homogeneity condition $AQ_AA + Q_BB = Q$ insure that implicit producer receipts $(w_aA = w_bB)$ equal commodity receipts (pQ).

so that the differentiated forms of equations (3) and (4) are

$$(3') \quad Ew_a - Ep + \frac{k_b}{\tau} EA - \frac{k_b}{\tau} EB = 0,$$

$$(4') \quad Ew_b - Ep - \frac{k_a}{\tau} EA + \frac{k_a}{\tau} EB = 0.$$

The set of eight equations (1′)–(8′) describes the equilibrium displacement of the eight endogenous variables $(Q, p, A, B, w_a, w_b, p_a, p_b)$. The only exogenous disturbance considered here is the change in ρ. The solution to the system can be obtained by row operations on the matrix to define two new equations, eliminating EQ, Ep, and the four component prices.[4] These two equations in EA and EB can be solved easily using Cramer's rule. Given the solutions for EA and EB, the solutions for the other variables are determined easily from the original equations. Below are the resulting elasticities of equilibrium prices and quantities with respect to changes in ρ, and the sign of these elasticities as derived in the following paragraph.

$$(15) \quad EA = -\frac{1}{D}\left[k_b\left(1 + \frac{1}{e}\right) - s_b\left(1 + \frac{1}{n_b}\right)\right]E\rho \geq 0,$$

$$(16) \quad EB = \frac{1}{D}\left[k_a\left(1 + \frac{1}{e}\right) - s_a\left(1 + \frac{1}{n_a}\right)\right]E\rho \leq 0,$$

$$(17) \quad Ew_a = \frac{1}{D}\frac{k_b}{\tau}\left(\frac{1}{e} - \frac{s_b}{n_b} - \frac{s_a}{n_a}\right)E\rho \geq 0,$$

$$(18) \quad Ew_b = -\frac{1}{D}\frac{k_a}{\tau}\left(\frac{1}{e} - \frac{s_b}{n_b} - \frac{s_a}{n_a}\right)E\rho \leq 0,$$

$$(19) \quad EQ = \frac{1}{D}\left[k_a s_b\left(1 + \frac{1}{n_b}\right) - k_b s_a\left(1 + \frac{1}{n_a}\right)\right]E\rho,$$

$$(20) \quad Ep = \frac{1}{D}\frac{1}{e}\left[k_a s_b\left(1 + \frac{1}{n_b}\right) - k_b s_a\left(1 + \frac{1}{n_a}\right)\right]E\rho, \text{ where}$$

$$D = \frac{1}{\tau}\left[\frac{1}{e} - \frac{s_a}{n_a} - \frac{s_b}{n_b}\right] + \frac{1}{n_b}\left[k_a\left(1 + \frac{1}{e}\right) - s_a\left(1 + \frac{1}{n_a}\right)\right] + \frac{1}{n_a}\left[k_b\left(1 + \frac{1}{e}\right) - s_b\left(1 + \frac{1}{n_b}\right)\right] \leq 0.$$

The indicated signs of these elasticities are reasoned as follows. For agricultural commodities, it will be true generally that the elasticities of demand for A and B are between zero and -1. Elasticity of supply e is positive as are all component shares, and τ is negative. From these assumptions, D is negative. To establish signs on the variables, arbitrarily designate A as the component with higher price under commodity pricing, as was illustrated in figure 1. Then, considering a displacement from the commodity pricing equilibrium M to the component pricing equilibrium N, ρ will increase from a value less than one to a value of one. Under these conditions, the signs of (15)–(18) are unambiguously established. The signs of EQ and Ep are identical, but are not determined a priori. Equilibrium commodity output will increase, however, if the elasticity of demand for A is sufficiently large relative to that for B.

The market problem in figure 1 is a special case of the problem just described, the case of $e = 0$, for which the production possibilities curve is fixed. Factoring $1/e$ from numerators and denominators and canceling, equations (15)–(20) yield the following when evaluated for the special case of $e = 0$:

$$(15') \quad EA = -\frac{k_b}{D_1}E\rho,$$

$$(16') \quad EB = \frac{k_a}{D_1}E\rho,$$

$$(17') \quad Ew_a = \frac{1}{\tau}\frac{k_b}{D_1}E\rho,$$

$$(18') \quad Ew_b = -\frac{1}{\tau}\frac{k_a}{D_1}E\rho,$$

[4] Specifically, define one new equation as the following combination of the original eight: (1′) + (1/e)(2′) − (k_a)(3′) − (k_b)(4′) − (s_a)(5′) + (s_b)(6′) + (s_b)(6′) + (7′). Define the second new equation as −(3′) + (4′) − (5′) + (6′) + (8′).

(19′) $$EQ = 0,$$

(20′) $$Ep = \frac{1}{D_1}\left[k_a s_b\left(1 + \frac{1}{n_b}\right) - k_b s_a\left(1 + \frac{1}{n_a}\right)\right]E\rho, \text{ where}$$

$$D_1 = \frac{1}{\tau} + \frac{k_a}{n_b} + \frac{k_b}{n_a}.$$

It is interesting to note the effect of the three elasticity parameters, τ, n_a and n_b, in this case. The smaller are these elasticities (in absolute value), the smaller will be the displacement of equilibrium M to equilibrium N in figure 1. As any one of these elasticities approaches zero, points M and N converge to the same point, and there will be no social gain from component pricing. This is intuitively reasonable, because if τ is zero, there is no production opportunity for changing the ratio of components in response to the new market signals. If either demand elasticity is zero, there is no willingness by consumers to accept other combinations of components. Hence, a highly elastic transformation curve alone is not a sufficient condition for changes in component ratios in response to component pricing.

The final analytical step is to determine the effect of the equilibrium displacement on producers, on consumers of commodity A, and on consumers of commodity B. Willig has shown that for most practical purposes, the area under the demand curve and above the price line serves as a precise measurement of the amount of income change which would be required to compensate consumers for a movement along the demand curve. If the demand elasticities are constant over the range of this movement, then this measure of consumer surplus change for a good is

(21) $$\Delta CS = \int_{p_2}^{p_1} \alpha p^n dp = \frac{\alpha}{1 + n} p_1^{1+n}[1 - (1 + Ep)^{1+n}],$$

where α is an arbitrary constant and n is demand elasticity. Expressed as a fraction of the original value of the good, the change in consumer surplus is

(22) $$\frac{\Delta CS}{p_1 X_1} = \frac{1}{1 + n}[1 - (1 + Ep)^{1+n}],$$

which is positive for price decreases and negative for price increases. Similarly, the change in producer surplus as a fraction of the original value of a commodity can be represented as

(23) $$\frac{\Delta PS}{p_1 q_1} = \frac{1}{1 + e}[(1 + Ep)^{1+e} - 1],$$

which is positive for price increases and negative for price decreases. In the case of $e = 0$, the change in producer surplus as a fraction of commodity value reduces simply to Ep.

The model described above provides a method of evaluating the potential gains and losses to consumer and producer groups from a movement toward component pricing—that is, a movement toward equality of component price ratios in consumer and producer markets. (Solutions to the model will not provide exact equilibrating market conditions, because the equilibrium displacements are evaluated at initial market shares.) The cost of implementing component pricing is not considered explicitly, though this consideration could be accommodated easily by specifying a simultaneous exogenous shift of the appropriate size in the processing margin, designated in the model as γ. A more serious deficiency of the model is that it does not address the question of the market equilibrium level of information about the component quality of commodity batches being traded. Thus, it provides no insights as to when component pricing will occur. Despite this limitation, the model is useful in evaluating the potential impacts of a change from existing levels of price wedges to a perfectly implemented component pricing structure.

Component Pricing of Soybeans

The model just presented was developed to examine the potential impact of a change in market information technology for agricultural products. New instruments utilizing near-infrared reflectance and nuclear magnetic resonance hold some promise as methods of providing quick, inexpensive, and accurate information about the protein and oil content of milk and soybeans at the point of first sale (see Niernberger, and Updaw and Nichols). The soybean market is particularly amenable to the component pricing model because soybeans are used almost exclusively for processing into soybean oil and soybean meal, and there are well-defined market prices for each of these

components. Under the current pricing system, each individual farmer sells soybeans to processors or country elevators on the basis of weight, generally adjusted only for moisture content. While it is likely that prices paid to all farmers are adjusted for differences in the average component content between producing areas or between crop years, prices paid to individual farmers are not adjusted to reflect the component content of his lot of grain. In effect, then, producers face a 1:1 price ratio for the oil and protein that are produced and sold with the soybeans.

The elasticities of demand for soybean oil and meal have been studied by several authors. The elasticity estimates for oil have not been very consistent, ranging from −4 (Brandow) to −0.3 (Houck, Ryan, Subotnik). Protein meal elasticity estimates have been only a little more consistent, ranging from −0.9 (Houck) to −.14 (Houck, Ryan, Subotnik). For this initial approximation of the impact of component pricing, demand elasticities are assumed to be −0.5 for both components. Soybean supply elasticity is estimated alternatively at 0 and 1.5. (A recent study by Gardner estimates the long-run supply elasticity for soybeans to be about 1.3.) Estimates of the elasticity of transformation between protein and oil production are not at present available though efforts are underway (Updaw). For this analysis, alternative elasticities of −0.5 and −1.5 will be examined. Of course, if the transformation elasticity is zero, there would be no change in quantities or consumer prices, but implicit producer prices would change.

The commodity pricing equilibrium taken as a point of departure is the simple average of annual prices and quantities during the four crop years beginning September 1974. These values, shown in table 1, indicate that the ratio of oil price to protein price in the component markets has been about 1.33. The implicit farm price of the components is taken to be the farm value of soybeans divided by the total pounds of oil and protein, or \$.19/lb. The value of ρ, the price wedge, is then 1.0/1.33 = 0.75, so the percentage change in ρ, which corresponds to a shift to perfect component pricing, is .25/.75 = .33. At the initial prices and quantities shown, oil represented a share s_a of .41 in the value of components derived from soybeans, but an implicit share k_a of only .34 in the farm value of soybeans since that is its share of component weight and the two components are implicitly priced equally.

The equilibrium displacements from a shift to component pricing are shown in table 2 in percentage terms and in table 1 in equilibrium quantities and prices. Oil production would increase by up to 8% and protein production would fall by up to 5%, depending on the elasticities assumed. Price changes are greater, due to the inelasticity of demands. These are

Table 1. Commodity Pricing and Component Pricing Equilibrium in the Soybean Market

Endogenous Variable	Symbol	Commodity Pricing Equilibrium	Component Pricing Equilibrium $e = 0$, $\tau = -.5$	$e = 1.5$, $\tau = -.5$	$e = 1.5$, $\tau = -1.5$
Soybean production (billion lb.)	Q	87.12	87.12	86.94	86.85
Oil production (billion lb.)	A	15.84	16.70	16.67	17.08
Protein production (billion lb.)	B	30.43	29.57	29.51	29.05
Farm price of soybeans (\$/lb.)	p	.101	.1004	.1009	.1008
Price of oil (\$/lb.)	p_a	.243	.2166	.2176	.2049
Price of protein (\$/lb.)	p_b	.183	.1933	.1940	.2000
Farm price of oil (\$/lb.)	w_a	.190	.2106	.2106	.2003
Farm price of protein (\$/lb.)	w_b	.190	.1793	.1793	.1846
Farm value of soybeans (\$ billion)		8.800	8.751	8.772	8.754
Value of components (\$ billion)		9.418	9.334	9.355	9.310
Change in:

Oil consumer surplus (\$ billion)			.430	.413	.628
Protein consumer surplus (\$ billion)			−.310	−.333	−.495
Net social surplus (\$ billion)			.072	.075	.125

Sources: USDA, *Fats and oils situation,* various issues. Oil and protein production are calculated from total soybean production and the yields of oil and 44% protein meal for those soybeans crushed domestically. Oil price is for oil in tank cars at midwest mills. Protein price is calculated from the price of 44% protein meal at Decatur. Initial farm price for oil and meal is calculated as the total value of soybeans at the farm price, divided by the sum of oil and protein production.

Table 2. Percentage Equilibrium Displacement from Component Pricing of Soybeans

Endogenous Variable	Symbol	Displacement of Equilibrium Values from Component Pricing		
		$e = 0$ $\tau = -.5$	$e = 1.5$ $\tau = -.5$	$e = 1.5$ $\tau = -1.5$
		(%)

Protein consumer surplus		−5.56	−5.97	−8.88
Net social surplus		0.8	0.8	1.4

rather substantial changes, and in terms of consumer surplus amount to gains to oil consumers of up to $628 million and losses to protein consumers of up to $495 million. If oil consumers actually compensated protein consumers for their losses, consumers as a group would be better off under component pricing, but without such compensation there is no basis in economic theory for deciding whether oil consumers are unfairly subsidizing protein consumers under the present pricing structure, or whether protein consumers would be unfairly penalized by the shift to component pricing. If the two groups were essentially the same persons, this equity question would be of less concern, but this is not entirely the case because oil is destined to consumers in the form of vegetable oils and shortenings, while protein is for the most part destined to consumers after being converted into meat by the livestock industry.

Ignoring this equity issue, the potential net efficiency gains (including the minor impact on producers) are small, at most about $125 million, or about 1.4% of the value of the annual soybean crop. It seems plausible that this is a sufficient gain to offset the additional costs of instruments and sampling efforts to implement component pricing, because the entire soybean marketing and processing margin is now only about 7% of the crop value. But if the elasticity of transformation is substantially less than −1.5, the net gains may be insufficient to offset the additional costs of component pricing. While this study does not address the question of whether component pricing would become the market-determined pricing structure, it is at least plausible that firms' incentives to price by components could lead to component pricing even if market efficiency were reduced. This corresponds to the possibility of socially excessive equilibrium levels of information suggested in other contexts by Hirshleifer and by Spence.

Component Pricing of Milk

Most milk marketed in the United States is priced on the basis of a base price for milk with 3.5% fat content, plus a premium or discount for each tenth of a percent deviation from this level. In some European countries and in a few marketing areas in the U.S., notably California, price is based on the content of protein or on solids-not-fat (SNF) as well as fat content. The past decade has seen a continued discussion of possible multiple-pricing schemes for the entire United States and their effects on different groups of producers and consumers (see Ontario Milk Marketing Board, and Smith and Snyder). Those who have favored multiple component pricing have argued that it is equitable to pay farmers on the basis of the value of the components that they produce, and that marketing efficiency is improved when producer prices more accurately reflect the preferences of consumers. None of the studies has attempted to evaluate the dollar equivalent of such efficiency improvements.

One reason for the lack of a definitive analysis of milk component pricing is that the various components (fat, protein, lactose, water, etc.) are not exclusively extracted and sold separately. While markets exist for some of the components, they are for the most part sold in products such as whole milk, ice cream, cheese, butter, etc., in which the components are not necessarily identified but do contribute to product quality. Therefore, the market value of every component is not readily observable, and a consumer goods characteristics demand approach (see Ladd) would be useful in establishing implicit consumer values for the various components. The California pricing system, however, is based on just three components, fat, solids-not-fat, and fluids, with the prices for the first two based on support prices for butter and for nonfat dry milk as announced by the U.S. Department of Agriculture, and the value of fluids determined as a residual (Ontario Milk Marketing Board, p. 37). The following analysis examines the potential impact of a similar two-component-pricing plan if it were introduced into areas currently under federal milk marketing orders, which currently account for about 60% of all U.S. milk production.

The average annual production of milk, butterfat, and SNF during 1974–76 in the federal order milk markets is shown in table 3. The implicit component prices faced by farmers are not obvious under the current fat-based pricing system. They were approximated for this study as follows. The average base price for 3.5% butterfat milk during this period was \$.0852/1b. The average fat content of all milk actually sold was 3.67% butterfat, and the average price paid for this milk was \$.0867. This implies that the average premium for extra butterfat was \$.882/1b. If the remaining value of milk during this period is imputed to SNF produced, then the price per pound of SNF was \$.630, so that $w_a/w_b = .882/.63 = 1.4$. In the component markets, the average price paid for butterfat in cream was reported as \$.77/1b., and the average price for nonfat dry milk was \$.61, giving the ratio of $p_a/p_b = .77/.61 = 1.26$. Now the relevance of this price ratio is debatable, because milk is not processed for sale exclusively as these components. As an alternative, component prices were calculated as the weighted average of the prices of milk products, with the fraction of the component sold via each product as weights. This yielded $p_a/p_b = .59/.46 = 1.13$.

Sources: USDA *Federal Milk Order Market Statistics, Annual Summary for 1977*. Figures are averages for the three market years 1974–76. Solids-not-fat production was calculated using the average content of all milk produced in the United States for those years (USDA *Dairy Situation*, May 1978). The price of butterfat is the average U.S. price reported for milkfat in cream, and the price of SNF is the average U.S. price for nonfat dry milk for those years, both as reported in *Agricultural Statistics, 1977*. The farm prices for components are calculated as described in the text from 3.5% butterfat blend price, total revenue and butterfat content as reported in *Federal Milk Order Market Statistics*.

Both of these sets of prices imply that the total value of the butterfat and SNF components of milk is less than the farm value, evidence of the oversimplification of the two-component model used here. But because these two estimates of the ratio do not differ greatly, for this analysis we estimate that the ratio of consumer prices for the two components is about 1.2. In any case, it appears that the current pricing structure overprices butterfat, the more valuable of the two components. The price wedge is about 1.4/1.2 = 1.17, which suggests that a shift to component pricing would result in a 20% reduction of ρ.

Estimates of the demand elasticities for the two components are not available. They have been calculated for purposes of this study as the weighted average of the elasticities of demand for the products in which they are sold, using the Hallberg-Fallert product-elasticity estimates and the share of component sold via each product during 1974–76 as weights. This procedure yielded estimates of −.5 as the demand elasticity for butterfat and −.4 for SNF. For supply elasticity, we use the Chen, Courtney, and Schmitz estimate of 2.5. As was the case for soybeans, there have been no studies of the elasticity of transformation between fats and protein in milk production. The Ontario Milk Marketing Board report cites many studies of factors affecting milk composition, but concludes only that transformation opportunities are limited at best and can only be achieved slowly (p. 2–5). Given this lack of empirical estimates, we will again consider alternative transformation elasticity estimates of −.5 and −1.5.

The impact on prices and quantities, in percentage terms, of a change from butterfat pricing to two-component pricing is shown in table 4. Equilibrium values are compared in table 3. Butterfat production is estimated to fall by at most 3% to 5% and SNF production to rise by at most 2%, with corresponding changes in component prices. Losses to butterfat consumers would be up to $184 million, about 9% of the current value of the component, while gains to SNF consumers would be up to $216 million, about 6% of the value of the component. Producers would gain in the case of fixed inputs, because production is diverted to the more price inelastic market, but not in the other situations. The annual increase in social surplus would not exceed $105 million, or about 2% of the value of milk production, less the extra costs of implementation. As was the case for soybeans, it appears that the potential improvement in net social gains is small, though there could be substantial transfers between consumer groups and perhaps among producers as well.

Summary

The general objective of this paper has been to determine the potential impact on producers and consumers of a movement toward more

Table 4. Percentage Equilibrium Displacement from Two-Component Pricing of Milk

Net social surplus		1.8	0.3	0.4

accurate component price transmission from consumers to producers in the soybean and milk markets. To describe the potential equilibrium displacements which would result from such changes, a market model was specified in which two components are produced jointly with constant elasticity of transformation, and in which the producer component price ratio and the consumer price ratio are separated by an exogenous wedge representing the accuracy of price transmission. It was shown that the size of the equilibrium displacement depends upon the elasticities of demand for the components, the elasticity of supply of the commodity, and the elasticity of transformation.

Under current soybean-pricing practices, farmers implicitly receive the same price per pound for oil and for protein; while in the component markets, a pound of soybean oil is worth about one-third more than a pound of soybean protein. The implementation of component pricing of soybeans at the farm level would have a negligible effect on producer returns, and would increase social surplus by an amount up to $125 million per year (about 1.4% of the value of the crop). Under current milk pricing practices, farmers receive an implicit price per pound for the fat component that is about 40% higher than the implicit price per pound for the solids-not-fat component. In the component markets, fat is also worth more per pound than solids-not-fat, but only about 20% more. The difference between these two figures reflects the extent to which the current butterfat-based milk pricing system overprices fat relative to solids-not-fat. The implementation of two-component pricing would appear to affect producer returns little if at all, and would increase social surplus by an amount up to $105 million per year (about 2% of the value of milk production).

The results of this analysis suggest that the social benefits attainable from the component pricing of soybeans and milk are small at best, being no more than one or 2% of the current value of these commodities. There are several reasons to believe that the gains would be smaller than even this estimate. First, the limited data available on the technological possibilities for changing component composition of milk and soybeans suggest that the transformation elasticity may be quite small compared to the estimates used here. Second, the additional transactions and monitoring costs for component pricing have not been deducted from these estimates, and we might well infer that these costs have been of sufficient importance in the past to discourage the adoption of component pricing by market participants. Third, the equilibrium analysis employed here has assumed that producers would know the component price ratio in advance of production decisions. To the extent that variations in this price ratio would lead to wrong expectations, the efficiency gains realized would be diminished.

Optimal Policies for Marketing Cull Beef Cows

William A. Yager, R. Clyde Greer, and Oscar R. Burt

Feeding and marketing strategies for cull beef cows were analyzed by formulating a stochastic dynamic programming model which allowed simultaneous determination of optimal selling time and feeding levels until sale. The state variables were cow weight and monthly price; the latter was estimated statistically as a first-order autoregressive process with parameters changing monthly. Results for Montana cow prices at Billings suggested substantial gains to feeding healthy cows through the winter instead of immediate sale after fall culling.

Key words: cull beef cows, dynamic programming, marketing alternatives.

Livestock marketing research has focused almost solely on the primary product of the beef cow-calf subsector, stocker and feeder cattle, while marketing the important joint product, cull brood cows, has received little attention. Beef cows are purchased and held for their value as productive assets. At the time cows are removed from the breeding herd, there are marketing alternatives; yet seasonal selling patterns suggest that once removed from the breeding herd, cows are disposed of immediately. If the firm is, in fact, attempting to maximize net return, then consideration of marketing alternatives for cull cows is worthy of attention because they constitute 15% to 25% of annual gross revenue.

At the time a cow is removed from the brood herd, her current market value, price times weight, is known within rather narrow limits. Slaughter cow prices at local auctions and terminals are known, and prices offered by country buyers, both packer buyers and speculators, can be discovered readily. While spatial price differences may exist, increased net returns usually cannot be realized by individual producers because of increasing transaction and transport costs for the relatively small lots sold (Erich, Glandt, St. Clair).

Marketing alternatives which might yield increased net returns would take advantage of existing patterns of seasonal price variation and the ability of cull cows to maintain body condition and achieve weight gains on high roughage rations. As is the case with many agricultural product price series, cull cow prices have exhibited very definite patterns of seasonal variation. Larson; Erich, Glandt, St. Clair; and Plaxico and James all report significant patterns of seasonal variation in slaughter cow prices. Prices are at their seasonal low in late fall and seasonal high in the spring. Larson concluded that slaughter cow marketing has not changed to reduce swings in seasonal variation to the extent that such changes have occurred among other livestock enterprises.

The methods of Foote and Fox were applied to fifteen years of slaughter cow-price data from the Billings, Montana, market (December 1960 through November 1975), and similar significant patterns of seasonal variation were found for each of the four slaughter cow grades, table 1. Prices were at their seasonal low in November and their peak in May or June, with the difference between the high and low price as much as 19% of the annual average price.

Seasonal price patterns, at least in large part, result from current marketing decisions. In many regions of the United States, and particularly in the range livestock areas, beef cows are bred to calve in the spring. Under a system of spring calving ranchers are most likely to cull cows in certain seasons; many old, poor-producing, or open cows are culled in late autumn when calves are weaned. Other

cows are culled in the spring after failing to calve or losing their calves or to adjust herd size as range conditions vary within a year. These production characteristics combined with immediate sale at culling result in significant seasonal shifts in cow supply.

Cows sold immediately at culling will be in a given body condition, depending upon the balance between feed nutrients provided and required during the immediately preceding period, which for cows culled in the fall is the calf-suckling period and for those culled in the spring is the wintering period when cold stress and later stages of gestation increase nutrient requirements. Only significant changes in management practices would provide an opportunity to alter body condition of cows at culling. However, with delayed sale alternatives, there is an opportunity to alter body condition and weight by providing alternative levels of nutrition to cows that have been culled and will be sold.

Marketing alternatives that delay sale increase costs and introduce risk and uncertainty into the problem. Additional costs for feed, labor, facilities, opportunity cost of capital, and sickness and death loss will be incurred during the holding period. The major cost is feed, which varies with cow body weight and desired weight change. Heavy cows require more feed for body maintenance, and cows of a given weight require relatively higher levels of nutrition to achieve rapid weight gain. Delaying sale and feeding for one of several rates of gain will be a preferred alternative only if returns are expected to increase. The return, which is jointly determined by unknown future values of two variables, cow price and cow weight, will be received as a lump sum when the cows are sold.

The discussion thus far had focused on seasonal price variation as the primary motive for delayed sale, but insofar as the long-term cyclical behavior of cattle prices can be forecast with sufficient accuracy, additional profits would be possible on the rising price period of the cycle. On the other hand, the falling price period of the cycle would reduce the opportunities of profiting from the typical seasonal increase in prices during winter months.

The purposes of this paper are (a) to develop an appropriate decision model for evaluating cull beef cow-marketing strategies, and (b) to present an application which suggests the magnitude of potential expected profits and general structure of the optimal decision rule. The relative order of magnitude of expected gains from a formal decision model compared to immediate sale of cull cows will indicate whether empirical refinements are worthy of attention.

The Decision Model

Evaluation of cull cow-marketing alternatives is considered properly in a stochastic framework because both weight gain and future prices are random variables. The marketing decision, what to sell, in terms of body weight increments, and when to sell, depends upon price and weight change expectations which are formed under the joint probability distribution of price-weight change. Further, there are

characteristics which suggest that the problem is properly formulated as a sequence of decisions rather than a once-and-for-all decision. It is, of course, the case that once a cow is sold there is nothing more that can be done to affect the return from that cow. But while a cow is being held after culling, changing conditions may well affect the return from previous decisions as well as expectations in such a way that another decision, feeding at a different level or selling immediately, is preferred over previous plans.

The cull cow-marketing problem is thus a stochastic dynamic decision process which at any point in time is summarized by values of certain critical variables—state variables—that completely describe the system. While there may be a relatively large number of variables necessary to describe completely the cull cow-marketing problem, it is argued here that two variables, cow price and cow weight, adequately describe the process. These two variables define cow value, and are continuous variables which, in the course of time, take on different values. With each new value of one or both variables—state transition—the system occupies a different state.

Thus, the decision maker considers current known values of two continuous variables as well as the conditional probability distribution for their future values. In cases where such uncertainty is important, it is often beneficial to delay decisions as long as possible, allowing results of previous decisions and changed values of state variables to be observed and incorporated into the decision process. In the present problem, for example, after cows are removed from the breeding herd, a choice between selling or holding must be made. If the choice is to hold, then a specific level of nutrition also must be selected. However, rather than prespecifying the length of the holding period and a level of nutrition for the entire period, at succeeding intervals—stages—state variables are observed, and these values serve as information in the decision process. The states are random and jointly distributed over time, such that each observation in time is information regarding the state that will occur next. At each point in time that new information relevant to the decision problem is received (stage of the process) a choice is made between selling or holding the cows; and if the decision is to hold, then a level of nutrition also must be selected. Thus, the problem is viewed properly as a sequential decision process.

Ladd and Williams have recognized the dynamic stochastic nature of the cattle-feeding problem in their investigation of feedlot management where a Bayesian decision model was selected as the method of analysis. While the states and stages specified were quite similar to those of the present problem, the number of possible states and stages was restricted severely because total enumeration of all possible state/stage combinations was used as a method of solution. The computational burden of this approach is obvious.

Dynamic programming, through the inductive backward solution technique, has been shown to be a robust, computationally efficient method for solving stochastic multistage decision processes under an expected value criterion. Determining an optimal decision rule for all possible initial states at the first stage of the process also determines an optimal policy for all states and stages of the process (Burt and Allison). Hence, with a one-year planning horizon, a dynamic programming solution to the rancher's cull cow-marketing decision in the fall will yield optimal marketing policies for cows that might be culled at any time during the year.

It would appear that an expected value criterion is appropriate for the cull cow-marketing problem because the net returns are small relative to the entire ranching operation. The associated variations under different marketing policies would constitute small enough changes in the rancher's wealth that a linear approximation to the utility function could be used without serious error.

Specification of stage length is quite arbitrary, but the model becomes increasingly complex as the stage length is shortened. We compromised by using a month. The actual structure of the model depends on the statistical behavior of the monthly price series used to estimate the probability distribution of future prices. The data suggested a first-order autoregressive relationship with separate parameters by months.

The recurrence relation of the stochastic dynamic programming formulation is

$$(1)\quad V_t(P,W) = \max\left\{PW, \max_k\left[-C(k,W) + \beta\alpha\int_0^\infty\int_{-\infty}^\infty V_{t+1}(X,W + 30G)h(G|W,k)f_{t+1}(X|P)dGdX\right]\right\},$$

where P is average cow price for the month

just ended; W is cow weight; G, daily rate of gain produced by the feeding level chosen; $C(k,W)$, cost of feed, labor, and facilities for the cow weight and feeding level chosen; $h(G|W,k)$, the conditional probability density function of gain, given cow weight was W and level of nutrition k; $f_t(X|P)$, the conditional probability density function of cow price, X, in month t given price in month $t - 1$ was P; α, probability that a cow will live one more month; β, discount factor, $1/(1 + i)$; t, month, 1 = November, 2 = December, . . . ; and k, decision alternative with respect to feeding level.

When the maximum in (1) is PW, the process makes a transition to a terminal state where $V_t(\cdot)$ is identically zero for any period t. Although we have α factored out from under the integral, the joint probability density function for the present value, $V_{t+1}(X, W + 30G)$, is $\alpha h(G|W,k)f_{t+1}(X|P)$, and $V_{t+1}(\cdot)$ assumes the value zero with probability $1 - \alpha$. The value PW appearing in (1) implies that a cow can be sold at the beginning of a month for the average price prevailing during the month just past. Within the limits of the discrete time model using a stage length of a month, this assumption seemed as reasonable as the only practical alternative of using expected price during the month just being entered.

The double maximization operation in (1) can be interpreted as follows. If the cow were to be kept one more month, the maximization with respect to k (the feeding intensity) would be necessary and the associated value appearing in (1) would be the expected present value of the cow if she were kept another month and an optimal policy followed thereafter. This value must be compared with PW, the expected present value from immediate sale; the maximum of these two values is $V_t(P,W)$.

The Empirical Problem

Twelve stages were specified with each stage corresponding to a month thirty days in length. The initial stage was November which, within the dynamic-programming solution technique, is the last stage of the computations. Under present management practices, November is the month in which the largest proportion of cows are culled and sold in Montana. Thus, the model determines optimal decisions for cull cow marketing in any month from November through the following October. The decisions are optimal subject to the condition that the cows must be sold by the end of October.

States

State variables describe the condition of the decision process and thus constitute the vector of attributes that determine current and future cow value. Current value is determined by cow price and cow weight which suggests these two variables as state variables. However, there may be additional information that is important to describing precisely the condition of the process and the transition of these two critical variables over time.

Cow weight depends upon health of the cow and her performance, as measured by the achieved rate of gain on the level of nutrition provided. At culling, some cows may be in poor health and their performance through the holding period would be different than the norm. While experimentation could provide the necessary death loss and rates of gain estimates, they are not currently available. In this study expected sickness and death loss and rates of gain were assumed to be constants. Thus, the results apply to healthy culled cows with the presumption that unsound cows would be sold immediately at culling.

Cow price is an essential variable for establishing value of the cull cow when ultimately sold. Any variables that help predict price one month ahead are candidates for state variables, in principle at least. For this study we selected a time-series approach to predicting future cow price rather than constructing a model that explicitly accounts for the determinants of supply and demand. Several specifications which included both autoregressive and moving-average terms after seasonal differencing (Box and Jenkins) were estimated using monthly average commercial cow prices reported from Billings, Montana, January 1960 through May 1976. A simple first-order autoregressive model which allowed both slope and intercept parameters to vary by month gave better results (standard error of the estimate equal 0.928) than the best model using the techniques of Box and Jenkins (standard error of the estimate equal 1.05). The first-order autoregressive equation was tested by predicting twelve months beyond the sample period and the root mean-square error of prediction was less than the standard error of the estimate from the regression equation. De-

flated cow prices gave a poorer fit and less precision than the raw data.

Since the primary objective of the study was to evaluate potential expected profits from cow disposal strategies, as contrasted to deriving practical decision rules, we did not pursue the forecasting research in much depth. In retrospect, we should have tried a logarithmic transformation of the data because the resulting model would have been more robust to changes in value of the dollar.

First-order autoregressive processes can track a cyclical sequence like we find in the cattle industry quite well if the cycle is long relative to the discrete time period being used. In monthly data, the cattle cycle would typically be 120 to 140 periods; therefore, the first-order process should not be seriously disadvantaged by the cattle cycle. The statistical analysis supported this conclusion with higher order lagged prices being quite insignificant.

Because the first-order autoregressive model elicits most of the information contained in the past prices, only one price state variable, current cow price, is necessary. The estimated equation was used to generate conditional probabilities for future observations (Nelson, pp. 18–19).

Feed prices can best be treated as a parameter instead of a state variable in the decision model for three reasons: (*a*) seasonal variation is relatively small in feed as compared to cow prices; (*b*) a short-term variation in cow price has a great deal of leverage on profit because the entire weight of the cow enters total revenue, while feed price only affects the profit margin during the time on feed, i.e., a quick sale can prevent losses when feed price goes up sharply but not when cow prices drop sharply; and (*c*) changes in feed prices can be hedged period by period as a decision is made to hold the cows on feed another period. These considerations make it possible to model the cow disposal problem with feed price as a parameter and solve the entire dynamic programming problem several times for various feed price levels. Then the decision rule, period by period, could be modified to include feed price as if it had been another state variable.

The tacit assumption in doing so is that feed price will be constant throughout the planning horizon, but as new information on feed price evolves, a new feed price can be assumed for the remainder of the process. Formally, we assume that feed price is a stationary first-order Markov process which is independent of other state variables and then apply a certainty equivalence approximation to that component of the decision model (Malinvaud). The certainty equivalence theorem would apply if feed price entered the expected immediate return function as a quadratic jointly with the decision variable, given the other state variables, but otherwise, only approximately. The stationarity assumption on feed price is also only approximate insofar as some seasonal price variation exists.

For purposes of this study, feed prices were collected through an informal survey of feed dealers and farmers and were assumed constant throughout the decision process.

Thus, two state variables, cow weight and cow price, describe the process at the beginning of a month under the assumptions stated above. Cow weight and cow price are both continuous variables but for computational purposes were divided into discrete units which were, hopefully, small enough to maintain the spirit of continuity. Cow prices within the range \$10.00 to \$30.00 per hundredweight (cwt.) were considered and divided into \$0.25 intervals. Thus, there were eighty-one possible prices: \$10.00, \$10.25, . . . , \$29.75, \$30.00. Cow weights within the range of 350 kilograms (kg.) to 597.5 kg. were considered and divided into intervals of 7.5 kg. Thus, there were thirty-four possible weights: 350.0 kg., 357.5 kg., . . . , 590.0 kg., 597.5 kg. The number of states was the number of discrete cow weights times the number of discrete cow prices, 2,754 (81 times 34), with state number one assigned to the combination cow weight 350.0 kg. and cow price \$10.00/cwt., state number 2 assigned to the combination cow weight 350 kg. and cow price 10.25/cwt., ... An additional state, number 2,755, described the state of the process when cows were already sold.

Decision Alternatives

The decision made in one stage controls the state of the process in the following stage. For any stage after a decision to sell cows has been made there are no alternatives and the decision process is terminated. Otherwise, one possible decision at any stage is to sell the cows. Alternatively, the decision may be to hold cows for later sale, in which case a decision must be made regarding the ration to feed. While rate of gain is assumed constant,

Table 1. Comparison of Time Series with Frisch Method Estimates of Demand Price Elasticities for Three Levels of Commodity Aggregation

Commodity	Time Series	Frisch	Commodity	Time Series	Frisch
		Group One			
Durables	−1.23	−1.23	Nondurables	−0.62	−0.62
Semi-durables	−0.69	−0.69	Services	−0.91	−0.92
		Group Two			
Food	−0.42	−0.48	Drugs and sundries	−0.78	−0.92
Tobacco and alcoholic beverages	−0.54	−0.64	Transportation and communication	−1.00	−1.15
Clothing	−0.52	−0.60	Recreation, entertainment, education, and cultural services	−1.09	−1.27
Gross rent, fuel, and power	−0.74	−0.84			
Furniture, furnishings, household equipment, and operations	−0..72	−0.83	Personal goods and services	−0.55	−1.27
		Group Three			
Beef	−.8522	−.4008	Margarine	−.6276	−.0786
Pork	−.9547	−.1053	Lard	−.4628	−.0769
Lamb	−1.8660	−.5203	Shortening	−.9680	−.1703
Veal	−2.5930	−.3966	Salad dressing	−.9270	−.2280
Chicken	−.5637	−.1156	Fresh fruits	−.4546	−.1754
Turkey	−1.0900	−.3993	Canned fruits	−.7498	−.3093
Fish	−.7929	−.1678	Fresh vegetables	−.2420	−.0702
Eggs	−.1207	.0000	Canned vegetables	−.3215	−.0837
Cereals	−.2000	−.1275	Sugar	−.2400	−.0909
Fluid milk	−.4390	−.1617	Beverages	−.3726	−.1210
Butter	−.8583	−.2222	Frozen foods	−1.0319	−.4134
Cheese	−.9077	−.4016	Prepared foods	−.6710	−.2544

Other dairy products	−.3300	−.0853			

Source: Frisch estimates were calculated by the authors based on Frisch [p. 186, eq. (61)] and income elasticity, budget proportion, and money flexibility (−1.30) estimates from Green et al. (pp. 100, 104) for groups 1 and 2 and Hassan and Johnson (1976, p. 41) for group 3 from which the comparable time-series estimates were also obtained.

suggestions by Houthakker, it appears that at both of these aggregation levels, the assumption of want independence would be valid.

At the bottom of table 1, it is apparent that the Frisch estimates differ substantially from the time series estimates for the individual food commodities or food groups. Of the twenty-seven time series price elasticities estimated, nine are directly from the regression analysis by Hassan and Johnson (1976). Of these, no Frisch-calculated elasticity is within one standard deviation of the respective time-series elasticity and only two (fish and canned fruits) are within two standard deviations. Slightly different time-series price elasticity estimates and standard deviations (from those ultimately used in the complete matrix) are reported by the authors for ten additional commodities. Of these, only the Frisch-calculated elasticity for eggs is within two standard deviations of the time-series estimate and none is within one standard deviation. If the differences between the Frisch and the time-series elasticities using the Canadian data are indicative of what is likely to occur with highly disaggregated commodities or groups, the Frisch method used by P-L-H appears to be inappropriate. The downward biased estimates agree with earlier theoretical analysis regarding the consequence of ignoring the combined effects of goods that are likely to be substitutes under non-want independence.

For a commodity whose budget proportion is low, e.g., most individual food commodities, the Frisch price elasticity has been shown to be approximated by the income elasticity divided by the money flexibility coefficient (Barten 1977, and Deaton). Given that most values of θ generated have typically been between −1 and −2 (Brown and Deaton, p. 1206), the use of this approximation generates price elasticities that are less (in absolute value) than their income elasticities. In fact, for individual food commodities, theory and empirical evidence would suggest that the converse is more likely true. Yet, in their two articles in this *Journal*, Pinstrup-Andersen and others present tables of

of the direct price elasticity calculated with the Frisch approach from the true e_{ii} will equal $\sum_{k,k \neq i} \sigma_{ik}$. Ayanian (p. 85) noted, "The possibility that, in the absence of want independence, $\sum_{k,k \neq i} \sigma_{ik} = 0$ (i.e., that the effects of complementarity just offset all substitution effects related to good i) would seem to be very small." If good i is a substitute of several other goods (as is likely to be the case for individual food commodities, e.g., beef, pork, eggs, etc.), then $\sum_{k,k \neq i} \sigma_{ik}$ will be greater than zero and the Frisch estimates will be biased. To ignore these combined effects because of the assumption of want independence would lead to estimates which are below the true elasticities. Ayanian found this to be in accord with Barten's (1964) findings that twenty of the twenty-two nonzero utility interactions were substitutions.

The calculation of the matrix of demand price elasticities requires estimates of the income elasticities, budget proportions, and the flexibility of money, θ. The method by whch P-L-H calculated θ is from Frisch's (p. 187) equation (64), which itself is based upon the assumption of want independence. The authors' six food commodities—rice, beans, tomatoes, oranges, sugar, and cooking oil—used for calculating θ are unlikely want independent. It is questionable whether the procedure was "certainly the best available, given the data constraints" (p. 136). Other methods are available for estimating θ. Although Bieri and de Janvry did not report an estimate for Colombia (as noted by the authors), estimates were available for other South American countries (Chile, Argentina). These estimates were higher (in absolute value) than the one finally chosen by P-L-H. De Janvry, Bieri, and Nuñez also suggest a formulation for estimating θ which the authors recognized but rejected because of exchange rate problems between countries. Whether the method suggested by de Janvry, Bieri, and Nuñez would have resulted in an estimate of θ that is poorer than one calculated with commodities which are not likely to be want independent is a question worth considering. More recently Lluch et al., suggested a formula for estimating θ based on national accounts data.

P-L-H's (p. 136) conclusion that their estimate of θ is below what would be expected from previous estimates of other countries and, furthermore, that it is inconsistent with Frisch's conjecture that the absolute value of θ decreases as the level of real income increases should cause them to suspect the applicability of using six individual food commodities for its estimation. The assumption of want independence is just not likely to hold at this level. Ayanian concluded that Frisch-calculated elasticity estimates were quite sensitive to decreasing values of θ, and that in particular the direct elasticities are likely to be $(n - 1)$ times more sensitive to errors in θ than are the cross-elasticities where n is the number of sectors (commodities) analyzed. If one has several estimates of θ, Ayanian has shown that the higher (absolute) estimates should be weighted more heavily in averaging to reduce the expected error.

In an attempt to evaluate empirically the appropriateness of the want independence assumption, we have calculated demand price elasticities of commodities (or groups) at three levels of aggregation using the Frisch method. These results are then compared with price elasticities estimated from time-series data. To the extent that the want independence assumption is correct, the resulting elasticity estimates using the Frisch approach should approximately agree with what one would estimate statistically if adequate time-series data were available.[1] It is usually not possible to judge the reasonableness of the Frisch-generated estimates, particularly in developing countries, because estimates from time-series data are not available as was the case in the P-L-H study.

Recent articles by Green, Hassan, and Johnson provide time-series estimates of price and income elasticities for (*a*) four highly aggregated groups of commodities—durable goods, semidurables, nondurables, and services, and (*b*) nine slightly less aggregated commodity groups, and by Hassan and Johnson (1976) for (*c*) twenty-seven individual food commodities or food groups similar to those in the P-L-H study in terms of their level of aggregation. An estimate of the flexibility of money of -1.30, which is used in the calculations below, was obtained for the four aggregated groups where the want independence assumption is likely to be valid.[2]

In table 1, estimates of the direct price elasticity from time-series data can be compared with those calculated using the Frisch method. It is readily apparent that the Frisch coefficients are nearly the same as their respective time-series values for the four most aggregated commodity groups suggesting that the Frisch method does quite well. For the middle aggregation level, the price elasticities calculated with the Frisch approach differ somewhat from the time-series estimates although in most cases, these differences are quite small.[3] Based on

[1] This, of course, assumes that elasticities generated from econometric demand models using time series are the "true," or closer to the "true," elasticity estimates. As O'Riordan showed, the results from various statistical demand models can themselves vary substantially; that is, estimates of a commodity price elasticity may vary due to different time periods, functional forms, or model specifications. Typically, however, time-series rather than cross-section or budget data are thought to provide researchers with better measures of systematic changes in prices and quantities for demand elasticity estimation.

[2] The estimated income flexibility (the inverse of the money flexibility, θ) reported was more than three times its standard error.

[3] Because Green et al., did not provide standard deviations for their estimates, no tests of statistical significance could be performed; however, due to the small differences it is unlikely that the Frisch estimates are statistically different from the time-series estimates.
